With so many excellent works on anatomy now before the profession, any new author venturing into the field must have the best of reasons for adding to the literature of the subject. The present work is in some respects a departure from the methods of study usually adopted, and in so far commends itself to the student. Viewed from the stand-points of morphology and physiology the subject is divested of much of its dry detail, and made proportionably interesting and practical. This part of the study, taken in connection with the evolution of form and the nature and arrangement of tissue, naturally leads to a proper appreciation of the fundamental principles upon which true anatomy is based. A very commendable effort is made throughout the work to apply the facts of anatomy to the elucidation of those problems in medicine, surgery, and physiology which are constantly presented to the student. While the author rightly acknowledges that there is little scope for originality in writing a text-book for students, he has done his best to give the descriptions an individuality, and consequent interest, by writing them in the dissecting-room with the cadaver before him. We confess, however, to some disappointment regarding the typography of the work. There is too much of the heavy black letter over the pages, while many of the illustrations are poorly executed, and in not a few the shading is much blurred. The diagrammatic sketches are exceptionally excellent, as illustrating many useful points in the arrangement of structure and in the relations of different tissues to each other. Many of these are original and give a practical turn to the work, and are of great value to the student.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 4, 1890.

F. P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

Excision of the Drumhead for Middle Ear Disease.—DR. SAMUEL SEXTON related the history of a case of deafness from chronic catarrh of the middle ear, in which the special point of interest was the fact that there had been unusual delay in keeping the drumhead open. The patient, a woman aged twenty-seven, had come to the infirmary in consequence of deafness and noises in the head, symptoms which had come on gradually, but had suddenly become more marked from cold, so that she was compelled to give up a situation as head-waitress. The symptoms continuing after she had been under observation for a time, he advised excision of the drumhead and larger ossicles. Ether was administered, the drumhead was excised in the usual way, the incus and malleus were removed. The trouble from noises and deafness improved very much, but in the course of three or four weeks the drumhead was reproduced, and it became necessary to remove it again, which was painlessly done without an anæsthetic. Simply a circular incision was made with the knife. The hearing was improved as before. Gradually, however, reproduction occurred a second time, and it was a third time performed, and collodion was painted over the edge of the wound, after which it healed. The patient was examined by him only a week ago, and he found the opening permanent. She had heard well enough for the past two years to resume her position as head-waitress. There had been no unpleasant symptoms at any time, except from the increased deafness during the temporary closure mentioned.

DR. WILLIAM M. POLK then read a paper entitled, "Mania and Multiple Neuritis in Pregnancy" (see p. 526).

DR. DANA said that besides the case reported by Dr. Polk, he had one other under observation. It was that of a woman aged thirty-eight, who had not indulged excessively in alcohol, though she drank moderately. Within one or two weeks after confinement she began to develop a painful atrophic paralysis involving all four extremities, but especially the lower. When brought to the hospital, about a month after childbirth, there was complete foot-drop and wrist-drop, and all the symptoms of a typical multiple neuritis. Mentally, she showed great weakness and aberration of memory, especially as to recent events; no delirium or actual insanity. The paralysis after about a month began to improve, and in three months was considerably better.

Besides the cases of multiple neuritis of pregnancy cited by Dr. Polk, Korsakoff had recently contributed a series in *Arkiv für Psychiatrie*, and had attempted to show that there was a peculiar form of insanity associated with multiple neuritis. This he calls a "toxæmic cerebral psychopathy." In the mildest forms there is simply irritation and enfeeblement, easy fatigue, tendency to morbid fears, insomnia, incapacity to keep attention, imperative conceptions, and sometimes there develops at once an acute mental disturbance, characterized by active sense of dread, anxiety, and fear, with hallucinations and delirium.

In the more fully developed and typical form, there are mental enfeeblement and irritability, with a characteristic confusion as to times, places, and incidents. There is forgetfulness of things recently occurred, while things that occurred some time before are remembered.

The form of insanity resembled so-called "alcoholic insanity." Dr. Dana doubted if Korsakoff had really succeeded in proving that the mental disturbance of neuritis differs from other types of toxic insanity. Korsakoff's cases were interesting; particularly as he shows that the multiple neuritis is sometimes masked by the mania, that it occurs in a slight degree, so that it is not observed after surgical operations, removal of tumors, etc.

CASE I.—Woman, aged twenty-eight. Symptoms of multiple neuritis began toward end of pregnancy. Gave birth to dead child at term. Then the neuritis and psychological symptoms rapidly developed, reaching height in a month. No pyæmia or septicæmia.

CASE II.—Female, aged twenty-two, childbirth, septic fever, pelvic abscess; about a month after birth of child, neuritis and mental disturbance. The neuritis hardly noted.

CASE III.—Woman, developed a month after childbirth; patient had septic fever, pelvic abscess.

CASE IV.—Woman, extra-uterine pregnancy; laparotomy, followed by multiple neuritis and mental disturbance, etc.

The speaker said in conclusion that the multiple neuritis in these cases was due, no doubt, to some poison in the blood, perhaps some kind of ptomaine or leucomaine. It was not due directly to the presence of microorganisms, at least so the bacteriological examinations of Rosenheim showed. But it had been shown that a bacteriological product like pyocyanin can cause neuritis.

Was the Murmur Mitral or Aortic?—DR. BEVERLEY ROBINSON thought some attempt should be made to explain the existence of the murmur in this case, for which a cause could not be found post mortem. The existence of the murmur as described, and the thoroughness of the post-mortem examination, could not be questioned in this case. He thought, therefore, that we would have to fall back on the explanation that the murmur was dynamic, and it might have been accompanied by a heart lesion which, he imagined, would in some cases be difficult to find after death. All would admit that murmurs were occasionally heard for which no cause could be found by the pathologist. Personally, he had never obtained much satisfaction from the explanation of cardiac murmurs based on the theory of certain blood conditions. He had been inclined to believe, and was more inclined to believe now than ever before, that in the heart itself was to be found the cause of such murmurs.

The Time of the Murmur.—With regard to the time of the murmur, that was very important. Was it really presystolic, coming from the mitral orifice, due to auricular contraction, or did it come from the aortic orifice, due in all probability to temporary dilatation, and so nearly presystolic that it could not be distinguished in time from the presystolic murmur accompanying auricular contraction? The observation of many men showed that the situation attributed to these murmurs in text-books was not entirely satisfactory. Clinically, we found that sometimes murmurs which were supposed to be presystolic, and hence indicating a lesion of the mitral orifice, were better explained by a lesion at the aortic orifice or by dilatation at that orifice. Therefore the locality of the murmur would not always enable us to say which orifice was affected.

Temporary Dilatation of the Cardiac Cavities.—There was no question, he said, that in acute conditions of various kinds, temporary dilatation of the cardiac cavities did sometimes occur. He could see no reason, therefore, why this bruit which appeared to be presystolic, and located in a region corresponding to mitral murmurs, could not have come from the aortic orifice, and be due to temporary dilatation which was not manifest at the autopsy.

He understood that there was incontinence of urine in this case, and evidence of inflammation in the bladder, and he asked Dr. Polk whether this was not considered a point in favor of some lesion of the spinal cord in contra-distinction to multiple neuritis.

The Chordæ Tendineæ and Heart Murmurs.—DR. HERMAN M. BIGGS suggested that the mitral murmur in this case might have been due to a chorda tendinea passing directly across the ventricle. This had been the cause of the murmur in two cases which had come under

his observation, in one the murmur being presystolic and in the other systolic. No cause could be found at the autopsy except a chorda tendinea running across the ventricle. This might readily have escaped observation, had one's attention not been directed especially to it.

Pregnancy Complicated by Peripheral Neuritis of Alcoholic Origin.—Dr. E. L. Partridge said he had not seen a case of peripheral neuritis which could be attributed directly to pregnancy. One woman had come under his observation who developed peripheral neuritis at about the third month of pregnancy, but back of it was an alcoholic history. She was delivered of a stillborn child at the seventh month, but the neuritis did not improve. She passed into a condition of alcoholic dementia and died.

Dr. J. West Roosevelt said that he thought it impossible to conceive of any narrowing of the mitral orifice, due to muscular contraction, which could produce a presystolic murmur. It was quite conceivable, however, that, owing to faulty action of the papillary muscles, the mitral curtains might fail to close perfectly during the first part of systole, and that this might permit of a short murmur, closely resembling in point of time the presystolic. Reduplicated first sound at the apex may be mistaken for a presystolic murmur. In regard to prognosis in cases of valvular heart disease, it must always be remembered that the questions to be answered in each case are: 1. How well is the heart doing its work? 2. If the heart works well, is there anything in the patient's general condition to indicate approaching degenerative change? 3. What valve is diseased, how much is it diseased, and is the disease such as to cause stenosis, insufficiency, or both?

A murmur means in itself but little. Whether there be a murmur or not, if the pulse is of good force when compared to the vigor of the heart-action, if the latter be not tumultuous or irregular, and, most important, if the pulmonary second sound be not accentuated, showing that the venous pressure in the lungs is not increased, the prognosis is good; unless there be signs of kidney disease, or signs of faulty heart-action shown by dyspnœa, or palpitation on exertion, or slight dropsy, or unless the patient be evidently suffering from malnutrition, or some chronic disease.

In regard to the condition of the valve, stenosis may be regarded in general as more serious than insufficiency of any valve. Withal, stenosis, mechanically, is necessarily much more serious than mitral insufficiency. The auricles do not possess much muscular power. There are, moreover, no valves at the entrance of the veins. Therefore, the left auricle is but little fitted to drive blood through a stenosed mitral valve. Dr. Roosevelt, in regarding prognosis, emphasized these facts: first, a murmur *per se* is a matter of little moment; second, the really important matter was to ascertain how the heart, as a pump, is doing its work; third, that obstructed pulmonary circulation, indicated by accentuated pulmonary second sound, is the most serious early sign of approaching danger.

Dr. Polk, in replying to the points raised during the discussion, said he was not prepared to deny that a chorda tendinea was not the cause of the heart-murmur, acting in the manner described by Dr. Biggs; he could only say that there was no mention of it in the post-mortem records. Had it existed it probably would have been found, for it was expected the case would be brought into court, and the gentleman making the autopsy anticipated a severe cross-examination.

With regard to incontinence of urine pointing to spinal lesion, on this point he and Dr. Dana had reached the same conclusion. Incontinence did not come on until the patient's mental condition had become seriously impaired; then she had a large, a pregnant uterus; owing to paralysis, she lay almost constantly upon the back. Therefore they were inclined to attribute the incontinence solely to mechanical causes; besides, a most careful examination failed to reveal any degeneration in the spinal cord or nerve-roots.

Regarding the explanation of the heart-murmur suggested by Dr. Robinson, it seemed to be based on the idea of functional dilatation caused by a low state of health. Against this view, however, was the fact that during the first pregnancy and before the second, the woman's health seemed to be perfect. He asked Dr. Robinson whether that met his suggestion.

Dr. Robinson replied that it did in part, but not wholly. We frequently saw persons who were apparently in perfect health, were unaware of heart trouble, when interference with the heart's action did actually exist. Such persons were capable on occasions of making great efforts, but the heart change was liable to manifest itself in an unexpected manner, at any time.

Dr. Polk had understood Dr. Robinson to mean that where these dynamic conditions of the heart existed, the general condition of the patient was at fault; that in such cardiac conditions one had to look to the general health rather than to heart symptoms.

The Significance of Cardiac Murmurs.—An interesting question was suggested by this case, namely, of what significance were cardiac murmurs? Here was a person who was extremely anxious to be married, but who was prevented therefrom for a considerable length of time by the opinion of an able diagnostician, who told her that if she should marry and have a labor it might be her last one. So far as the members of her family were concerned, they anticipated her labor with as much anxiety as they would her execution. Was there, then, any indication which would enable the physician to say to his patient that her cardiac murmur was an evidence of a dangerous condition? or that, on the other hand, it was of no moment whatever? It certainly proved to be of no moment in this patient.

A Cardiac Murmur of Itself of Little Significance.—Dr. Robinson thought the fact had come to be pretty generally recognized that a cardiac murmur of itself meant very little. It came down to the question whether the heart was doing its work well. There were certain ways of determining that point aside from physical signs. One evidence of lack of proper compensatory power was difficult breathing; a second was palpitation; a third was pain in and around the heart. If the heart was neither hypertrophied nor dilated, and there was no renal nor other physical evidence that the heart was suffering, the mere presence of a cardiac murmur should not be considered as of great importance.

Dr. Polk thought the conclusion reached by Dr. Robinson an important one, and one which he would be happy to accept; but as a matter of fact we found mitral stenosis giving rise to scarcely any symptoms at all until the latter months of pregnancy, and then, when it was too late to accomplish much, cause very serious symptoms, sometimes indeed terminating the patient's life.

Dr. Robinson thought the point made by Dr. Roosevelt a good one, and said that he should listen to the heart at the same time of feeling the pulse, comparing the one with the other.

The Value of the Sphygmograph.—Dr. Kinnicutt remarked that many physicians were getting out of the habit of using the sphygmograph, and were relying as formerly on the touch to determine the characteristics of the pulse. If the sphygmograph was capable of indicating anything, it ought to be of service in mitral stenosis. He asked Dr. Roosevelt his opinion on these points.

Dr. Roosevelt said that he regarded sphygmographic tracings as of the same, but of no more, value than the written descriptions by skilled observers of the pulse as ascertained by touch. The sphygmograph is not an instrument of precision, but as a means of record which is valuable in skilful hands.

Dr. Andrew H. Smith inquired of Dr. Polk whether, from the point of view of the obstetrician, the danger was greater in mitral stenosis, or whether it was greater in mitral insufficiency.

Dr. Polk replied, that in practice it did not seem that the danger was greater in the one than in the other; yet mitral stenosis was generally regarded as the cardiac lesion above all others likely to cause trouble during labor.

Dr. A. H. Smith thought that much regurgitation would have a similar effect, namely, to force the blood back on the lungs.

Dr. Polk said that was true, but patients with dilatation to that extent did not usually wish to get married.

Dr. A. H. Smith thought that a practical test would be the patient's ability to go upstairs without distress; her ability, in other words, to bear the extra pulmonary strain.

Danger of Placental Apoplexy. — Dr. A. A. Smith thought the question of danger from marriage in patients having a heart-murmur assumed a wider range than was suggested by the presence merely of such a murmur. Was there danger of the development of pulmonary complications, of renal complications, or of placental complications? Within four years he had had two cases of albuminuria in pregnant women suffering from mitral obstruction. One aborted at the sixth month from placental apoplexy, it being the third time that she had aborted at this period from the same cause. He had seen her on two of the occasions.

The President remarked that the sphygmograph, if of any value in diagnosis, might be of supplementary assistance in the recognition of mitral stenosis.

A systolic murmur in the second left interspace, with maximum intensity an inch and a half to the left of the left sternal line, was not infrequently present in mitral stenosis, and was believed by certain distinguished observers, to be due to the compression of the pulmonary artery by the dilated auricular appendix. As its true origin was still unsettled, the diagnostic value of such a murmur in mitral stenosis, was of very doubtful nature.

Multiple Neuritis.—The President reported a case of multiple neuritis occurring in a boy aged eleven. There was a history of an illness of doubtful nature preceding its development. Marked paralysis of the extensors of both hands and flexors of the feet was present Exquisite sensitiveness in the course of the nerve-trunks of the affected parts existed, with vaso motor and trophic disturbances. The case presented many interesting points, which would be published in detail at a later period.

May a Woman with Heart Disease Marry?—Dr. A. A. Smith inquired of Dr. Polk what advice could be given a young woman who wished to marry and had cardiac disease—aside from the points already brought out in the discussion, which applied to heart disease in general.

Dr. Polk said his mind was very clear on this subject. If the lesion was confined to the heart he would offer no objection to marriage. If, on the contrary, the lesion had extended beyond the heart, he would strongly advise against it. A woman with a patch of congested lung tissue, an hypertrophied liver, and a contracted kidney, could not be considered as in a condition fit for matrimony. But confine the lesion to the heart, and he thought we had no right to assume that she was going to be afflicted with the dangers which we had been taught to look for. In the first place, she was not likely, after marriage, to become pregnant. Many of these women were subjected to endometritis, which was likely to prevent conception, or, if this did take place, abortion was likely to follow. The cardiac condition would not affect her seriously until she had passed the fourth month. The chances were, if pregnancy continued that long it would go on to the seventh month, and then, if thought necessary, premature labor could be brought on, with the birth of a living child. Our means of differential diagnosis, and of medical and surgical treatment, had so far improved of recent years that we were better able to carry these women safely through the duties of matrimony than formerly.

Dr. Partridge was much inclined to agree with Dr. Polk. He thought, however, it was not meant there were no cases of heart disease in which it was not safe for a woman to marry, except where pulmonary congestion, œdema, or enlargement of the liver had taken place. He believed there were cases of heart disease, with commencing dilatation and degeneration, which would make it unwise for the woman to marry, although lesions had not developed outside of the heart.

Dr. Polk said no; that if the patient was not suffering from any secondary effects of the heart trouble, he would assume the heart was in good enough condition to justify marriage. In other words, if the heart was in good enough condition to enable the woman to retain good general health and soundness of the other organs, it was sound enough to meet the exigencies of marriage and pregnancy, when guarded by modern improvements in surgery and therapeutics.

Dr. Partridge thought that the advice which had been given women with heart disease was largely based on tradition, much like that which had been given women mildly insane to marry, with the idea that they would recover. He had seen, as others present doubtless had, women go safely through labor once or a number of times, when they had a lesion of the mitral valves or other heart lesion. He remembered once attending a woman in confinement who had an active pulmonary congestion, and had to be delivered in a sitting posture. She subsequently had another child.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 12, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Tubercular Peritonitis with Latent Symptoms.—Dr. L. Emmet Holt presented some specimens removed from a boy two years of age, with the following history:

The patient had been under observation in the Babies' Hospital, where he was admitted two days before death. The father was reported to be sick with pulmonary tuberculosis in Charity Hospital. There was no history of tuberculosis in other members of the family. The child was stated to have been well until an attack of pneumonia, three months before, from which he had never fully recovered. He had continued to cough and lose flesh, and had not been able to walk about. During the last few weeks enlargement of the abdomen had been observed. On admission there were found the evidences of rickets quite well marked, the tongue was coated, cervical glands slightly enlarged, but no change in any other external glands. There were signs of partial consolidation throughout the left lung, particularly behind and in the lower portion. The abdomen was much enlarged and everywhere tympanitic, but there were no evidences of fluid, and no pain or tenderness even on deep pressure. There was no enlargement of the spleen or liver. The superficial veins were not enlarged. There was moderate cachexia. The boy was poorly nourished and small for his age, weighing but eighteen pounds. During the time that he was under observation he lost steadily in weight. The stools were never more than three in number in the twenty-four hours, but all contained a good deal of mucus and were foul-smelling, though they contained no blood. There was no vomiting, and the boy appeared to digest his food well. The rectal temperature ranged from 98.4° to 99.4° F., never rising above the latter point until within a few hours before death, when it reached 100.2°. The child coughed rarely. There were never any evidences of pain. The child lay or sat quietly in his crib, usually listless and indifferent to his surroundings. He had the appearance of a child suffering from malnutrition, but nothing more. The prostration gradually increased and finally passed into collapse, in which the child died.

Autopsy.—The brain was not examined. The left lung was generally adherent both to the chest-wall and to the diaphragm; the adhesions were firm, old, and organized, but there were no tuberculous deposits in the pleura. In the lower part of the upper lobe, and in the whole of the lower lobe, there were very many large and small tubercular nodules, some of which were broken down; considerable new connective tissue was present. The right lung was slightly emphysematous, but in general nearly normal, except that a few tubercular nodules, small and widely scattered, were found; there were no adhesions. The bronchial glands were enlarged and cheesy, and some were broken down. The heart and pericardium were normal.

Peritoneum.—Both the visceral and parietal layers of the peritoneum were universally involved. The omentum was from one-eighth to one-sixth of an inch thick, firmly adherent both to the abdominal wall and to the intestines, and filled with tubercular deposits. All the intestinal coils were firmly united by not very old plastic product, which could be easily separated. The liver was so firmly adherent to the diaphragm that its substance was torn in removing it. The spleen was likewise bound in position. No portion of the peritoneum seemed to have escaped, and in the exudation everywhere were very extensive tubercular deposits. Several small pockets were formed between the adhesion which contained brown turbid serum; about half a pint in all was collected from the abdominal cavity. The liver was moderately fatty, and contained no tubercles except upon its surface. It did not respond to the iodine test for amyloid degeneration. The spleen was firm and not enlarged; a very few tubercular deposits were seen on section. The kidneys were normal.

Intestines.—The small intestine contained great numbers of tubercular ulcers, the largest less than an inch in length, extending transversely in the gut. In several places these had extended to the peritoneal coat, and one had possibly perforated during life, although the adhesions were so firm and so abundant that the tear might have been accidental. The ulcers were generally situated in Peyer's patches. The large intestine contained no ulcers and its mucous membrane was essentially normal. The mesenteric glands were all enlarged and cheesy, and some were beginning to soften. None was larger than half an inch thick and one inch in diameter.

The special points of interest about this case were in the first place, the absence of symptoms with so extensive a pathological process. All the usual symptoms, such as pain and tenderness, fever, ascites, and the presence of abdominal tumors, were wanting. Dr. William Osler, in his excellent monograph upon this subject (Johns Hopkins Hospital Reports, vol. ii., No. 2, 1890), calls especial attention to the frequency with which tubercular peritonitis has been found at autopsy, or during abdominal sections, when it had never been suspected. In the case reported it does not seem possible to have made a diagnosis. A second point of interest was the extent to which the peritoneum was involved, without any very recent process in other parts of the body. Of the 357 cases collected by Dr. Osler, only 27 were in children under ten years of age, so that the disease cannot be said to be very often seen at this time of life. The speaker had seen two other cases of the disease in young children, but never before such a generalized form as in the case presented.

Dr. J. S. Ely thought that the point of entrance of the tubercle bacilli had been the lungs, as is the rule in these cases. This opinion was strengthened by the clinical history, as the first symptoms of any sickness in the child were referable to pulmonary trouble. He believed that tubercular sputum had been swallowed by the child, and had given rise to the peritoneal disease after absorption from the intestine. One of the most difficult things to explain, if this is the sequence in these cases of tubercular peritonitis, is the absence in many cases of any very extensive tuberculous lesion of the intestine. This was a feature of the present case. The peritoneal lesion was very marked, while in the intestine only a few small ulcers were visible. An explanation which had just suggested itself to the speaker, and which he would offer as little more than a suggestion, was the following: We know that in milk-fed children the contents of the alimentary tract throughout its whole extent are acid. In adults, and in children fed upon a mixed diet, the contents of the duodenum, jejunum, and upper part of the ileum are undoubtedly alkaline, but in the lower part of the ileum they have been found to be frequently acid. This is the location of Peyer's patches and of the solitary follicles, through which it is customary to suppose the tubercular bacilli to be taken up. Now, it is a well-known fact that the tubercle bacilli do not grow upon acid media. While in the intestine, and while in Peyer's patches, bathed constantly by the acid contents of the intestine, may they not be checked in their development until they have been carried beyond their incompatible surroundings, into the alkaline medium of the lymphatics and blood-current? Then they would have every opportunity to develop.

Dr. H. M. Biggs said that an argument against this theory seemed to him to exist in the extensive tubercular ulceration of the gut so often found in cases of phthisis.

Dr. Ely replied that, on the contrary, this was rather confirmatory than otherwise, as the contents of the small intestine have been shown only occasionally to be acid, in the majority of cases being alkaline when the person is on a mixed diet. It is because cases like that presented by Dr. Holt are the exceptions that they need explanation, and the acidity of the contents of the intestine is the exception also. Another point in substantiation of this theory was the great rarity of tuberculosis of the colon and rectum where the secretion is acid, and the reaction of the fæces is also acid.

Abnormal Position of the Vermiform Appendix.—Dr. J. S. Ely presented two specimens which had been sent to the Museum of the College of Physicians and Surgeons within the past two days, showing an abnormal position of the appendix. In one case it was coiled up along the cæcum and hidden by the ileum, so that only its proximal end was visible. In the second specimen the vermiform appendix was not visible at all, and was distinctly retro-peritoneal. The specimens were interesting in connection with cases of appendicitis in which there is a retro-peritoneal abscess instead of a peritoneal one. He had once seen a similar specimen in which there were two perforations, but no peritonitis.

Urine with High Specific Gravity.—Dr. J. H. Linsley reported a case in which the urine had a very high specific gravity. The patient was a woman, twenty-five years of age, whose mother had died of heart disease, her father, three brothers, and one sister of phthisis. She herself had always enjoyed good health. She was first seen on February 23d, at which time she had been sick for two weeks. She complained of headache, anorexia, dulness, and general malaise. There had been no marked chill. During several days the temperature ranged from 101.5° to 104.5° F., and the pulse from 112 to 120. The urine was examined three days later, with the following result: Reaction, acid; color, reddish-yellow; odor, fetid; consistence, limpid; specific gravity, 1.050. It was cloudy and had a white or slightly flesh-colored precipitate. The quantity of urea was 0.0033 grm. per cubic centimetre, or 3.3 per cent. The chlorides were diminished, while the phosphates were enormously increased. Microscopical examination showed pavement epithelium, uric acid, amorphous phosphates, and the ordinary bacteria. The interest in the case centred in the high specific gravity, with the proportionally small amount of urea. Supposing the quantity of urine voided to have been 1,500 c.c., taking into consideration the specific gravity and the absence of sugar, the quantity of urine would have been 49 grammes, the normal quantity being 30 to 40 grammes for the twenty-four hours. The exact quantity of urea

was not known, but it was considerably below the normal. Another curious fact was the presence in the same precipitate of uric acid and amorphous phosphates. The excess of phosphates (which formed the precipitate) could be cleared up by adding a few drops of nitric acid; while upon the addition to the urine of a small quantity of liquor potassæ or ammonium hydrate, an enormous quantity of phosphates was precipitated. Dr. Linsley said that he had not had time to consult the literature on the subject to determine the rarity of this case, but in three thousand consecutive examinations of urine he had never seen any such condition as this, and on consulting with several pathologists he had ascertained that they had never observed any specific gravity as high as this in urine free from sugar. The specific gravity was taken not only with a urinometer carefully tested and corrected, but also with a Mohr-Westphal balance at 15° C. Since the time when the urine was examined first, up to the present, the patient's temperature has ranged from 100° to 104° F., and her pulse has always been above 100. She has had no eruption on the abdomen, and no marked symptoms of typhoid fever—in fact, an examination of all the organs gave a negative result. The specific gravity of the urine has not fallen as yet below 1.030 in any one specimen examined, and the excess of phosphates has continued.

In reply to a question whether any investigation had been made to determine the quantity of ash, Dr. Linsley replied that there had not.

Primary Carcinoma of the Gall-bladder.—Dr. H. P. Loomis presented a liver removed the previous afternoon from the body of a woman aged forty-six, who had been in excellent health until about four months ago, with the exception of an attack, two years before, which had been diagnosed as "gall-stones." This sickness lasted two weeks, and the woman made a good recovery. Four months ago she began to have pains in the region of the liver, accompanied by nausea, vomiting, loss of appetite, and progressive emaciation. About one month ago the attacks of pain became more frequent and more severe, and extensive jaundice developed. The urine contained bile, a small amount of albumin, and granular casts. The patient grew steadily weaker, although the nausea and vomiting were not marked at this time, and nourishment was easily retained. Various diagnoses of cancer in different organs were made by various physicians. No tumor was at any time appreciable, but the patient had the characteristic cancerous cachexia well marked.

Autopsy.—The stomach was not dilated, no obstruction at the pylorus was found, and the mucous membrane presented the appearances of subacute gastritis. The gall-bladder was entirely obliterated and its place was occupied by a cancerous mass the size of a small apple, in the centre of which were half a dozen gall-stones. Continuous with this was a second cancerous mass which extended upward and backward into the right lobe of the liver, nearly to its upper surface. There were no nodules in any other part of the liver, which was itself not enlarged, and the changed gall-bladder was so concealed by the free border of the organ that it would have been impossible to diagnose its condition during life. Microscopical examination of a section cut so as to include the nodules and some liver tissue of normal appearance, showed that the cancer-cells followed the capillaries in between the liver-cells, and collections of cancer-cells were seen in sections of the larger bile-ducts. The points of special interest in the case were: 1. The primary development of cancer in the gall-bladder and the non-involvement of the stomach and pancreas. 2. Although the extension of cancer into the liver was, without question, principally by continuity, still the finding of bile-ducts filled with epithelioid cells beyond the cancerous area would suggest that these biliary passages also furnished channels for the advance of the cancer-cells. 3. The question of the causal relation in which gall-stones stand to the development of cancer of the gall-bladder is brought up by this case. Dr. Loomis said that he believed, basing this opinion on clinical experience, that most cases of cancer of the gall-bladder give a history of repeated attacks of biliary colic extending possibly over a number of years.

Acute Exudative Endocarditis.—Dr. Loomis also presented a heart removed from the body of a woman, aged twenty years, who had died in Bellevue Hospital. She had been admitted with the symptoms of severe cardiac disease. The dyspnœa was so intense that she was unable to lie down. Her previous history was unobtainable, as she could not speak any English. During the ten days that she was in the hospital her temperature ranged between 102° F. and 105° F., the pulse was about 128, and the respirations were from 34 to 50. Physical examination of the lungs showed labored breathing, about normal pulmonary percussion, feeble and harsh respiratory murmur on both sides of the chest, and a few moist râles at the base of both lungs. At no time did she have a cough. Four days after admission the physical examination revealed the presence of fluid in the right pleural cavity, and this was confirmed by means of the exploring trocar. A needle being introduced again, a large syringeful of clear blood was withdrawn. Examination of the heart revealed a loud-blowing, mitral, regurgitant murmur, conveyed to the left and heard behind, between the fifth and eighth dorsal vertebræ. Examination of the urine did not give any evidence of disease of the kidneys.

Autopsy.—The left ventricle of the heart contained a mass of partly coagulated blood, presenting the appearance of an ante-mortem clot. The mitral valve was almost entirely destroyed. Vegetations, the size of small olives, projected from the valvular flap, and an ulcer, the size of a ten-cent piece, had eaten completely through one of the leaves of the mitral valve. The vegetations were soft and had all the appearance of being recent, and presented irregular wreaths enclosing the attachment of the chordæ tendineæ. Microscopical examination of sections cut so as to include the vegetations and part of the valve, and stained according to Gram's method, showed no bacteria. The heart-wall and the other valvular orifices were normal. There was no fluid found in either pleural cavity, so that the syringeful of clear blood that was withdrawn must have come from the needle piercing the congested lung. Both lungs had a pale-grayish, leathery appearance under the microscope, and showed scattered patches of catarrhal pneumonia, with intense congestion of the intermediate portions. The liver was of normal size, and showed the lesions of passive congestion. The kidneys presented the same changes. In the spleen, which was slightly enlarged, there was an infarction about the size of a large olive. From a careful examination of the cardiac lesion, Dr. Loomis said that he believed the process was acute from the beginning, and not an acute process engrafted upon a chronic one. No evidences of the bacterial origin of the endocarditis could be found either in stained sections of the destroyed valve or in cultures made in gelatine. Another interesting point in the case was the rapid disappearance of the serum which was demonstrated, not only by physical examination, but also by the exploring trocar, to have half filled the right pleural cavity.

Dr. Biggs, referring to the first case, believed that the cancer had extended chiefly by continuity, and did not think that the bile-ducts were the channels of its extension.

In regard to the second case, he thought that there were no such forms of endocarditis occurring without the presence of micro-organisms. He had always found some forms of pathogenic micro-organisms in these cases, and it seemed to him entirely impossible for anything else to excite an inflammation with destruction of tissue in a serous membrane. When we have destruction and ulceration, he believed that we must have the presence of micro-organisms.

The President said that he thought there was a tendency to attribute a little too much to the action of micro-organ-

isms, and to assume that they must necessarily be present in every case. He believed thoroughly in the pathogenic action of bacteria, yet it seemed to him that when a competent observer has tried to obtain cultures, and has made many sections in any particular case, but has found no bacteria, we ought to accept the evidence as reliable. A point of interest in the case was the fact that serum had been found in the chest at one time, and that it had disappeared not very long after. It showed how quickly serum might be absorbed at times.

Dr. Myers asked how much serum one might expect to find in the lung, and whether if we drew a drachm we would say that that was more than could be obtained from the lung alone. He had several times drawn thirty or forty minims of bloody serum in children, and after death he had been unable to discover any signs pointing to a previous exudation of serum in the pleural cavity.

The President said that he did not know how much serum might be drawn from the lung during life, but he had found it very difficult to get any appreciable quantity in this way after death.

Rachitis—Pachymeningitis Interna Hæmorrhagica.—Dr. William P. Northrup presented some specimens and microscopic sections removed from the body of a male child, aged twenty-three months, admitted to the New York Foundling Asylum at the age of one week, in "fair condition." It was put out to nurse, and returned to the Asylum in wretched condition, anæmic and emaciated. There were râles over both chests, the abdomen was prominent, the spleen was so large that it could be plainly felt. There were no signs of syphilis, and no convulsions or other symptoms of brain trouble.

Autopsy.—The body was emaciated, abdomen flabby and prominent, rachitic rosary well marked, epiphyses of the long bones not especially enlarged. On removing the skull the dura mater was found adherent to the bone, there was hemorrhage into its layers, and at the vertex more or less exudate upon its surface (pachymeningitis interna hæmorrhagica). The lesion was extensive, most marked at the vertex, and extending continuously to the base, where it gradually faded out. The least marked lesions were simple punctate hemorrhages within the substance of the dura, the most extensive lesion was the exudate upon the surface, rather thicker than blotting-paper. There were no thrombi in the sinus. There was extensive broncho-pneumonia (recent) in the left lung, and some marginal consolidation in the right. There were no cheesy masses in the lungs, though the glands were slightly swollen. The liver was enlarged and pale, but not fatty. The spleen was four or five times its natural size, and on section was dry and glistening, not waxy. There was no prominence of the Malpighian bodies. The kidneys were pale and the markings were distinct. The heart was flabby, and the foramen ovale was slightly open, but the ductus arteriosus was closed. The femur, when sawn longitudinally, showed an irregular line of ossification at the lower end of the shaft, at its juncture with the cartilage. There was an irregular bluish-gray zone, shading off from cartilage to ossified shaft. The zone of imperfect atypical ossification was two millimetres in width.

The points of especial interest in the case were: 1. The extensive pachymeningitis. 2. The imperfect, atypical intra-cartilaginous ossification. 3. The case was an excellent example, taken altogether, of rachitis in a child of twenty-three months. Pachymeningitis is not given by the authors as a usual complication of rickets, and seems in this case to have been rather a natural accompaniment of the depraved general blood condition.

Chylous Ascites.—Dr. H. M. Biggs showed a bottle containing some fluid from a case of chylous ascites. The patient was addicted to alcohol, and gave a history of gradually developing cirrhosis of the liver. The fluid removed at the first tapping was perfectly clear, but the fluid that oozed through the trocar opening was white like that presented to the Society. No fat could be seen on examination of the fluid under the microscope, although chemical examination shows the presence of fat in fluid of this kind.

The Society then went into executive session.

Correspondence.

"JUSTICE TO HOSPITAL GRADUATES."

To the Editor of the Medical Record.

Sir: Under this heading, in the Medical Record, April 19th, Dr. R. Ellis attempts to apply the *reductio ad absurdum* to Dr. Abbott's proposition to establish the degree of Hospital Graduate (H.G.M. or H.G.S.). It seems to me that his criticism is unwarranted and fallacious.

If out of every ten graduates of a medical college two serve a term as hospital *internes*, they are better fitted to begin the practice of medicine than are their eight colleagues. This fact is appreciated by the general public. Nor can it be injurious to the elder practitioners—whose attainments are well known and appreciated by their large *clientèle*—if the clinical advantages possessed by these two young men are recognized in the degree of Hospital Graduate.

In Philadelphia we have a few men who never graduated at any medical college, but on account of many years of practice were recognized as physicians under our Registration Law. One or two of these men could claim the degree of C.G. (Clinical Graduate) suggested by Dr. Ellis, but would he abolish the degree of M.D. simply because in their cases it means nothing?

Dr. Ellis says "Let our colleges and medical schools give degrees gained only by hard work, and let the matter end there," etc.

Theoretically this is true, but practically it seems unattainable—hence the necessity for State Examining Boards.

The fact is that the competition among medical colleges will effectually prevent the uniform or general granting of degrees "gained only by hard work."

To stop the overcrowding in the medical profession, and to elevate the standard of medical education in this country, the profession must determine the standard of fitness to practise medicine outside of, and free from, the dictation of medical college faculties.

The appointment of State Examining Boards is a step in the right direction, and the establishment of the degree of H.G. would be another step in advance.

The colleges would be forced to abandon didactic for clinical methods of instruction, and the standard of admission would be so raised as to exclude all who had not a thorough preliminary education.

Ultimately it would result in the survival of the fittest of our medical schools, and a lessening of the rush to obtain an M.D.

In the degree of H.G., therefore, we have nothing to lose, but may score a strong point for higher medical education.

T. H. Carmichael, M.D.

4467 Main Street, Germantown, Philadelphia.

To the Editor of the Medical Record.

Sir: In your issue of April 5th there appears an article over the signature of Dr. George E. Abbott entitled "Justice to Hospital Graduates." It will no doubt be in the nature of a revelation to the profession to be informed that these worthy gentlemen have all these years been suffering from injustice, but if it shall appear that they have let us see to it that justice is meted out to them—*fiat justitia ruat cælum.*

The doctor is evidently a great worshipper of titles. The old and comprehensive M.D. is not sufficient in his estimation for the favored mortal who has had the extraordinary advantages of a twelvemonths' residence in a hospital.

In order to distinguish him from the common herd he suggests that, in addition to the doctorate, the title of (H.G.) Hospital Graduate be added. Now, of course, there can be no valid objection to this. Let him have a string of titles as long as his arm if he wants them. Vanity is an inherent quality, peculiar to man and the genus *Pavo*. In the medical man this quality frequently manifests itself in the parade of titles on all occasions; a practice harmless enough in itself, even if it does provoke an occasional smile from the vulgar and irreverent, who refuse to see anything particularly awe-inspiring in a string of capital letters.

Dr. Abbott, in the course of his plea for "justice," makes the following unique and remarkable suggestions:

"For example: A patient desires to go to a strange town, and asks your advice as to whom to consult there; you take the 'Directory' and look up the various practitioners in that town, but can form no idea of the men, except that Dr. A. graduated at such a college in such a year. If, however, you could see among them, So-and-So, M.D., Harvard, '84, H.G.s. St. Luke's, '86, you would know that he is probably the best man to whom to send a surgical case; or if H.G.M., a medical case. Or, if we see So-and-So, M.D., Physicians and Surgeons, '84, H.G.s., Woman's Hospital, we know that of course he is the best man to whom to send a gynecological case. The title of H.G. (Hospital Graduate), if adopted, would represent a preparatory fitting in study, experience, manual dexterity, and in all other respects of far greater value to the community than does the average undergraduate course with its M.D., and very often of greater value than five or ten years of general practice. Adding to this indication of H.G. the letter s. for surgical, or M. for medical, would inform one of the nature of his preparatory work; and adding the name of the hospital would still further indicate the character of his experience."

Now I have no doubt that "So-and-So, M.D., H.G.s.," etc., would be a very competent man to treat a surgical case, but might it not be barely possible that there is someone else in "town" without the title of H.G.s.—just a plain M.D.—who could as successfully adjust the fracture or reduce the luxation? Again, might there not be someone in "town" who could treat a case of colic quite as scientifically as "So-and-So, M.D., H.G.M.?"

But when we come to a gynecological case we must not proceed rashly, for Dr. Abbott emphatically says that "So-and-So, M.D., H.G.s., Woman's Hospital," is, of course, the best man to whom to send this case, and the doctor ought to know, for does he not modestly inform us that he is himself an *alumnus* of the Woman's Hospital?

I do not wish to depreciate in the slightest degree the value of hospital training; on the contrary, it is a most desirable preliminary for the general practitioner. But it is not, however, as Dr. A. would have us believe, an indispensable condition to success and fame. In almost every community may be found men who, although never *internes* in a hospital, are nevertheless thoroughly competent to treat any medical or surgical case they may be called on to attend. Indeed many men of this class have risen to eminence in the profession.

Marion Sims could not write H.G. after his name, but nevertheless he emerged from his obscurity in the pity..,wing of their undermined condition, they could two overcome; a certain other proportion, again, died of pelvic abscess, peritonitis, etc., the cause of which was never determined. I speak positively of these last two conditions from personal observation, and I may add that since I some time ago made this statement, which seemed to be accepted at that time with doubt by some, I have had the satisfaction of having my views confirmed several times by others, who made a careful investigation at the post-mortem table. A second question is: Why is it that so many patients with diseased uterine appendages get well with ordinary treatment?

[1] Read before the New York Academy of Medicine, Obstetrical Section, April 24, 1890.

FEMALE PHYSICIANS FOR INSANE WOMEN.

To the Editor of the Medical Record.

Sir: I was much surprised to read in an editorial of your issue of May 3d these words:

"It is a very well known fact that, as a rule, women do not want to be attended by women doctors, and it is hardly fair to take advantage of their lunacy to impose such upon them by law."

If this statement were true, it would be impossible to explain the continued increase of "women doctors," who find so many women who do wish to be treated by them as to afford continually increasing incomes to their physicians.

The statement really illustrates the logical vice, known as "the undistributed middle," where a particular is interpreted as a universal and deductions drawn from it as such. There are *some* women who do not, "as a rule," wish to be treated by women doctors; yet even these often prefer to be treated by some women, or in some emergencies.

In the bill under discussion there is nothing that would prevent any female patient from profiting by any special or superior skill that might exist among other than the female members of the medical staff. But "it is well known" that such special skill, as estimated by any scientific standard, is extremely rare in American insane asylums. These are rather "asiles" for the guardianship of the insane than hospitals with any pretence for their treatment. As guardians, it is impossible to deny that women are intrinsically more suitable than men to take charge of insane women. The popular basis upon which largely rests the movement for placing such guardianship in the hands of women is, on the one hand, belief in their superior kindness and conscientiousness; on the other, the fact that the prevalence of erotic manias and tendencies among insane women renders the attendance upon them of men physicians often difficult or even impossible.

This quite apart from the question, which I think is still *sub judice*, whether it is often necessary or desirable to submit such patients to gynecological treatment. It is further "well known" that for poorly paid physicians a relatively higher grade of women is usually obtainable than of men. This is shown in the comparative ability of male and female teachers in our public schools. So few positions are open to women: so many women, moreover, shrink from the struggle of open competition in the world, and prefer a fixed position in an institution, that a supply of women capable of fulfilling existing requirements is likely to be larger than that of men who should be equally capable and equally willing.

It is strange to object, as the writer of the editorial does, to filling the position of assistants with "recent graduates" when "it is so well known" that this at present is the universal custom. In the City Insane Asylums on our Islands I have heard of junior assistants having been effectively selected, even before they had passed their final examinations.

The only reason for making it obligatory upon insane asylums to appoint woman physicians is, that all experience has shown that there is most likelihood of official opposition to women wherever there are any special reasons to be urged in their favor. The only medical society in New York City that ever refused to admit a woman physician to membership, and that after her paper had been accepted by the committee on admissions, is the Obstetrical. The Woman's Hospital is the one hospital in the city where the physicians have voted against the eligibility of female candidates for the post of assistants, and, I think, Dr. MacDonald is the only superintendent of an insane asylum who has ever taken the initiative in appointing women assistants. Where there is obstinate unreasonable, and tacitly organized opposition to the just claims to recognition of any class of people, it must often be overcome forcibly, or not at all.

Unquestionably, however, appointments of women physicians, as of men, should only be made after examination, and this should be, whenever practicable, competitive.

In an asylum in this State to which the civil service rules were professedly applied the papers of a female candidate were sent to me for examination. I unhesitatingly rejected her as incompetent and illiterate. It subsequently appeared that this candidate was a nurse or matron, whom the superintendent, when compelled by some outside pressure to nominate a woman physician, had put in the place of one, not expecting that an examination of proficiency would be demanded. When I returned the papers, condemned, to the Examining Board, the place was declared vacant, the vacancy advertised, and subsequently filled by an extremely capable graduate of the Woman's Medical College of the New York Infirmary. Yet this young lady, who passed an excellent examination, and who proved herself fully qualified for the duties of the position, was persistently snubbed by the superintendent who had been so well satisfied to nominate a thoroughly incompetent person, and thus evade the intention while apparently obeying the spirit of his mandate.

I am, sir, yours respectfully,

MARY PUTNAM-JACOBI, M.D.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 27 to May 3, 1890.

JARVIS, NATHAN S., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Camp Wade, Kingfisher, I. T., to take effect on the expiration of his present leave of absence, and will report in person to the commanding officer, Fort Verde, Ariz. Terr., for duty at that station. S. O. 102, par. 12, A. G. O., May 1, 1890.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. By direction of the President, will report in person to Brigadier-General Wesley Merritt, President of the Retiring Board, at Fort Leavenworth, Kan., for examination by the Board. S. O. 99, par. 4, A. G. O., April 28, 1890.

MCKEE, JAMES C., Lieutenant-Colonel and Surgeon. By direction of the Secretary of War, granted leave of absence for one month and fifteen days. S. O. 98, par. 4, A. G. O., April 26, 1890.

LA GARDE, LOUIS A., Captain and Assistant Surgeon. By direction of the Secretary of War, the ordinary leave of absence, granted in Orders 70, current series, Fort Assiniboine, Mont., is changed to a sick leave; and the extension of said leave on surgeon's certificate of disability granted him in S. O. 43, April 14, 1890, Department of Dakota, is further extended one month on surgeon's certificate of disability. S. O. 97, par. 5, A. G. O., April 25, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 3, 1890.

WOOLVERTON, T., Medical Inspector. Detached from Navy Yard, Washington, D. C., and to wait orders.

BEARDSLEY, G. S., Medical Inspector. Ordered to the Navy Yard, Washington, D. C.

HARVEY, H. P., Surgeon. Detached from the Ranger, to proceed home, and wait orders.

HEFFENGER, A. C., Passed Assistant Surgeon. Ordered to the Ranger.

GAINES, J. H., Surgeon. Detached from hospital, Hot Springs, Ark., and granted sick leave.

SPRATLING, L. W., Assistant Surgeon. Ordered to hospital at Hot Springs, Ark.

BOGERT, E. S., JR., Assistant Surgeon. Ordered to the Vermont.

OLCOTT, F. W., Assistant Surgeon. Ordered for examination preliminary to promotion.

AUZAL, E. W., Passed Assistant Surgeon. Detached from the Yantic and to resume duty on board the Galena.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 3, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	1
Scarlet fever	80	12
Cerebro-spinal meningitis	2	2
Measles	317	27
Diphtheria	94	28
Small-pox	0	0
Varicella	14	0
Cholera	0	0

The Eiffel Tower as a Mother's Mark.—The Paris correspondent of *The Medical Press* is responsible for the story that a woman from St. Quentin visited (being at the time about four months' pregnant) the late Paris Exhibition. One of the sights which seemed to strike her the most and to have an extraordinary influence on her nervous system was the celebrated Eiffel tower. Small blame to the poor woman! Recently she was confined, and the child bears on its chest a well-defined reproduction of the monument.

Unauthorized Quotations.—It seems that our English brethren also suffer from the unauthorized use of their names and garbled quotations from their writing in the advertisements of patent-medicine venders and others. The following from *The Medical Press and Circular* may interest some sufferers on this side of the water: "It is really urgent that some legislative restrictions should be placed on the disingenuous and unjustifiable use made by quacks and others of more or less garbled quotations from the works of well-known men of science. As matters are at present, the most disreputable individual is apparently at liberty to intercalate such expressions of opinion in such a way as to mislead the public into believing that this or that nostrum has received the personal approbation of the author. To render the fraud more telling, the phrasecology is usually modified and the sense distorted, and the injustice of the original proceeding is thus enhanced . . . If a man's name has a commercial value—not to put it on more ethical grounds—surely he ought to have the power to discuss the conditions under which he will allow it to be used. Scientific men are specially subject to this form of *exploitation*, and they ought to be able to command sufficient influence to secure the adoption of a plan for rendering the repetition of such unscrupulous manœuvres impossible, or at any rate

SIR: In your issue of April 5th there appears an article over the signature of Dr. George E. Abbott entitled "Justice to Hospital Graduates." It will no doubt be in the nature of a revelation to the profession to be informed that these worthy gentlemen have all these years been suffering from injustice, but if it shall appear that they have let us see to it that justice is meted out to them—*fiat justitia ruat cœlum*.

The doctor is evidently a great worshipper of titles. The old and comprehensive M.D. is not sufficient in his estimation for the favored mortal who has had the extraordinary advantages of a twelvemonths' residence in a hospital.

SALPINGO-OÖPHORECTOMY AND ITS RESULTS.[1]

BY H. J. BOLDT, M.D.,

NEW YORK.

WHEN seeking for the best method of treatment of any particular disease or pathological condition we are guided to a certain extent by statistics which show the results of various remedies employed in supposed similar conditions, and it is the object of this paper to give such report on the remedy indicated in the title, applied to some inflammatory and non-inflammatory conditions of the uterine appendages, and to elicit in the discussion the experience of some, whom we know to be in a position which affords them good opportunity for observation of the subject under consideration.

In a discussion before the Academy of Medicine, Dr. Coe cited some of the serious ultimate results of abdominal operations which he had observed, some of which have also been seen by others, but the occurrence of them does not mean that the operation should be abandoned; this knowledge should make us very careful to see that the patient to whom the operation is proposed has a condition which, we know by experience, requires such treatment to restore her to health and a life of usefulness.

It is high time that we compare the results of removing the uterine appendages with the results of other treatment; and should this investigation turn the scale invariably in favor of non-surgical treatment, by all means let us abandon the knife entirely. Such comparison must, however, be made by those who have had experience with various forms of other treatment properly employed on the same patient.

Yet no one will deny but what radical operations have been done formerly which the same surgeon, with his increased experience, would avoid to-day; but is it different with other departments of surgery or medicine? New operations and medicaments are grasped with enthusiasm by many of the profession as the panacea for the respective ailment for which they are praised, only to fall into oblivion with personal and reported experience.

The first question naturally asked by pronounced opponents to salpingo-oöphorectomy is: What became of the women in former years, before such operation was in vogue? Surely the same diseases must have existed then. If the gentlemen could have watched those afflicted with conditions in which I urge the necessity of an operation, it would have been found that they dragged themselves along a life of chronic invalidism until after the menopause, or the appearance of some other acute disease which, owing to their undermined condition, they could not overcome; a certain other proportion, again, died of pelvic abscess, peritonitis, etc., the cause of which was never determined. I speak positively of these last two conditions from personal observation, and I may add that since I some time ago made this statement, which seemed to be accepted at that time with doubt by some, I have had the satisfaction of having my views confirmed several times by others, who made a careful investigation at the post-mortem table. A second question is: Why is it that so many patients with diseased uterine appendages get well with ordinary treatment?

[1] Read before the New York Academy of Medicine, Obstetrical Section, April 24, 1890.

Let us bear in mind the development of the tubes from embryonic life to puberty; in this development we find a partial solution of the problem. Unless we keep before our eyes the different anatomical phases which these organs undergo, from the moment that the ducts of Müller form to the time of puberty, we cannot scientifically comprehend the pathology, symptomatology, and rational treatment of diseases of the Fallopian tubes. But it would be out of place to consider the subject in this article, and I would refer you to a most valuable contribution by Wilhelm A. Freund, "On the Indications of Operative Treatment of Diseased Tubes," in Volkmann's *Sammlung klinischer Vorträge*, No. 323, in which he vividly describes, with words and illustrations, the serious consequences of abnormal conditions during the development and descent of the tubes.

To further answer the last question, it must be remembered that many cases that are treated get only a temporary relief; they are thought to be cured, and are frequently so reported by the respective physician. The truth is, that when the ailment returns, with its former or greater severity, many of these patients drift into other hands. Where is the operating gynecologist who has not had such cases come to him in either private, clinical, or hospital practice? And who has not operated upon patients for the removal of pyo-salpinx, and the same patients were treated previously with rest, hot douches, tampons, massage, or electricity? But we must not forget the individual sensitiveness of recognizing the condition of the respective adnexa to warrant their removal, which cases do not require operation, but will do as well and better with some of the various forms of local treatment, etc.

To this latter class unquestionably belong the majority of women in whom the entire tubal canal is patent and the opening pervious or only slightly agglutinated, so that the contents of the tube, be they pus or other secretions, can be drained per the utero-vaginal canal, with and after dilatation of the cervico-uterine cavity; either after the method of Doleris [1] or that practised by Gottschalk [2] and advocated by Polk [3] for chronic endometritis. Also the greater number of those suffering with catarrhal salpingitis, and the ordinary form of ovarian inflammation. Yet there are not a few who suffer most intensely, so much so that life is a burden to them, who have been treated for months, perhaps years, with the best therapeutic agents known to us at the present time; but they have a return of the symptoms of a pelveo-peritonitis almost regularly. It is in such cases that the removal of the adnexa is crowned with the best results, even though the disease be not suppurative.

Allow me to quote only one of many examples from a letter to me from a patient in an Eastern State, who had her adnexa removed a short time ago. "No words of mine can express my gratitude for having been delivered from this sickness, from which I have suffered so much during the past years."

There were many cases in my practice upon whom I had spent weary months with treatment, and when by good fortune a period passed with much less pain, they and I thought, "At last we are successful;" however, at the next period it would be the old, old story, rolling in agony for from three or four days to two weeks. After operation they

[1] Nouv. Arch. d'obstetr. et de Gyn., No. 6. 1889.
[2] Deutsche Medicinalzeitung, No. 30. 1889.
[3] Transactions of American Gynecological Society, vol. xiii., p. 282.

were, as they expressed themselves in several instances, "new-born;" they once more could walk without being bent up, and were not afraid to ride in a street car or carriage for fear of a jar. Will anyone say that electricity, massage, or any other treatment cures such cases, "melts the adhesions?"—an expression which I have heard several times recently regarding the former treatment. All had been tried faithfully and properly.

It is obvious that the physician who not only sees but who actually carefully observes many patients with diseased adnexa per annum, and who perhaps has operated on a number of cases, is more competent and trustworthy to decide upon treatment, than the physician who treats only few cases and seldom or never operates. There is, however, one error into which the best diagnostician may fall, when intestines have prolapsed into the cul de sac of Douglas, and become fixed there by adhesive inflammation, so that the examiner would expect to find a dilated tube on operation.

Now let us look for one of the causes why some opponents decry salpingo-oöphorectomy almost without discrimination. We frequently hear of a patient on whom this operation has been performed, and she has derived but little or no benefit, perhaps feels worse. She passes into the hands of the general practitioner or electro-therapeutist and is cured. It is argued by those physicians, that had that line of treatment been adopted previously without operation such patients would also have been cured and not be minus their adnexa. This may hold good for some cases, but I deny that such suggestion will hold the test on any case which has been personally observed by me in my own or in the practice of others.

Why should those patients frequently not be relieved by the operation alone? Why are they cured subsequently by the same local treatment which before gave no relief, or but a temporary improvement, only to relapse again in a comparatively short time?

There is not a case of severe salpingitis, especially those of gonorrhoic origin, which is not accompanied by perimetritic adhesions to a greater or less extent. The starting-point of the perimetritis is invariably the diseased tube, and according to the intensity of the inflammation and the time of its existence will be the severity of the perimetritis; when such appendage is released from its adhesions we will still have perimetritis remaining; not only that, but a fresh exudation forms as the result of tearing those adhesions, so that when these women are examined some time afterward, we frequently feel an exceedingly sensitive exudate, which is occasionally an encapsulated blood-cyst. It is in this condition that the subsequent local treatment, the exciting pathological condition having been removed, will give a permanent cure.

One would be disappointed if he thought that a patient would have complete relief in a few weeks after operation for chronic tubal inflammation; such occurs only in exceptional cases. Health and entire freedom from pain is not restored for a number of months, in some cases perhaps a year or more; this is due to the long and intense suffering which these women have endured, the whole system having been undermined. Much can, however, be done to shorten the continuance of the local pains so frequently present, if the patient is treated locally and generally, as already noted.

It is also important, in case the condition makes it essential to establish the menopause in the respective case, to remove all of the ovarian stroma; though the tubes are removed, the monthly uterine congestion continues for a long time, as can be seen from the cases in which a portion of the ovary remained; to this A. Martin also calls attention by the case cited by him in his article "Zur Pathologie der Eileiter."[1] This, I think, is confirmed by every operator who has had such cases.

In cases accompanied by many adhesions we are also more apt to get subsequent trouble from adherent intestines, either with each other or to the floor of the pelvis. However, adhesions may form after the simplest kind of an abdominal operation.

Regarding the influence of any particular remedy on adhesions, I have seen two instances in which, at the time of opening the abdomen the first time, it was an utter impossibility to accomplish anything on account of the extensive adhesions existing. Within one year subsequently I had the opportunity to see the intra-abdominal condition again, and to my surprise all adhesions had disappeared. Had these patients been treated with electricity, such result would have been ascribed to it; but no such claim could be made, the patients having been under my personal observation, and the treatment consisted only of good food and a tonic. We know from this that adhesions can and will disappear of their own accord, but why it should be so in some cases and not in others I am unable to explain.

Knowing, as we all certainly do, that some very serious consequences may, and do not infrequently, follow, not immediately to the operation, for that does not often occur in the hands of the experienced operator, but as an ultimate result, it behooves us to look carefully into each case, and not be content with the mere diagnosis of "tubal disease," and then do the operation.

I have always insisted upon the necessity of keeping under observation and treatment the women afflicted with chronic salpingitis, a number of months, and avoid the use of the knife until satisfied that nothing less than the removal of the diseased adnexa will effect a cure. Not so with some acute affections.

Freund, in commenting on my article on "Interstitial Salpingitis," in which I state that I invariably advise immediate operation to patients suffering with puerperal pyo-salpinx, says, that if these cases will first have overcome the puerperal process, leaving only the tubal suppuration behind, they most frequently go on to a spontaneous cure, either with or without rupture of the abscess into the bladder or rectum. He means by this that operative interference is unnecessary. I must differ. If the inflammation is active, although usually the point of rupture is where he states, there are exceptions; it may burst into the abdominal cavity. Again, how much these tubal abscesses after rupture try both patient and physician we all know, and therefore I prefer and advise radical treatment before it has taken place; that is, for all acute cases in which a much distended tube can be recognized. By looking over the appended table, you will find many chronic cases of pyo-salpinx noted, where I state that the probable cause is the puerperal state; this cause is given because, 1. No gonococci could be found in the pus contained in the tube. 2. That by the most careful cross-questioning, no history of infection could be elicited. For such chronic cases the advice of immediate operation is not meant.

The psychical disturbances produced by the operation vary. I have not seen a single case that did not have vertigo, or complained of a full feeling in the head at times—in short, symptoms of cerebral congestion, to which also Dr. H. C. Coe called attention about two years ago. In one case it was so intense that for a number of months it was necessary to resort to venesection and withdraw from one hundred and twenty to two hundred grammes of blood, that being the only remedy which afforded relief. In the greater number of cases with severe disturbance large doses of potassium bromide, either alone or in connection with the use of the Paquelin cautery applied in the nape of the neck, gave a satisfactory result.

This psychical disturbance is the only condition which I have found more marked by the artificial production of the menopause than when the "change of life" comes about naturally. The changes in the genitals, physique, etc., are in my experience identical. I have noted the occurrence of purpura hemorrhagica in one case of sal-

[1] Deutsche medicinische Wochenschrift, 1886, No. xvi., p. 253.

pingo-oöphorectomy, and once after double ovariotomy for ovarian cystomata. Fresh hemorrhages occurred daily about the time of the former menstrual period, for three to four or five days.

Pelvic abscess has been observed but one time after operation in this class of cases. Fistulæ not at all. I attribute this to the non-use of silk for tying the pedicle. Catgut is used exclusively.

Ventral hernia is also a very rare occurrence in my practice. Of the laparotomies done for removal of the appendages, only one patient acquired this malady, to my knowledge.

If we study the cases upon which salpingo-oöphorectomy has been performed it at once becomes clear to us that both the immediate and ultimate result very much depends upon the condition for which it is done, and the cause and duration of the illness.

The observations upon which this contribution is based are the following one hundred and twelve cases, with eight deaths.

Laparotomies for Removal of Pyo-Salpinx.

Number.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Both appendages or right or left removed.	Time of illness.	Adhesions.	Drainage.	Immediate result of operation. Recovery or death.	Probable exciting cause of suppuration.	Ultimate result of operation on the condition of the patient.	Remarks.
	1885.												
1	Jan. 4.	35	M.	6	1	B.	3 mos.	Yes.	Yes.	R.	Puerperal.	Cure.	Had one abortion three months previously; third month gestation. Drainage-tube removed on the second day. Fever; wasting of patient; sweats.
2	Feb. 7.	33	M.	....	....	B.	12 yrs.	Yes.	No.	D.	Gonorrhœa.	....	Patient was a prostitute of the lowest grade; died on the second day of acute nephritis.
3	Feb. 24.	18	S.	....	....	B.	1 yr.	Yes.	No.	R.	Gonorrhœa.	Cure.	Had three fresh gonorrhœal infections within two years.
4	April 6.	21	M.	....	....	L.	3 yrs.	Yes.	No.	R.	Syphilis.	Improved.	Three years previously had a small non-painful sore on the labia minora, and soon after that a diffuse eruption appeared, which, however, disappeared without treatment.
5	April 11.	34	M.	6	....	R.	4 yrs.	Yes.	Yes.	D.	Puerperal.	.....	Death on the third day from septic peritonitis. The much distended and densely adherent tube ruptured during operation. Left tube enlarged, but did not seem to contain pus.
6	May 23.	29	M.	1	1	R.	3 yrs.	Yes.	Yes.	R.	Syphilis.	No improvement.	Gives history of having had syphilis seven years ago. Complains of severe pain on the left side, where the tube can be felt very much enlarged.
7	June 2.	37	M.	5	1	L.	2 yrs.	Yes.	No.	R.	Puerperal.	Cure.	
8	June 18.	26	M.	3	....	B.	3 yrs.	Yes.	Yes.	D.	Puerperal.	....	Fourth day, from sepsis.
9	July 14.	26	M.	1	....	L.	9 mos.	Yes.	No.	R.	?	Cure.	
10	Dec. 28.	25	M.	5	....	B.	17 days.	Yes.	Yes.	R.	Puerperal.	Cure.	Last child born three weeks previous to operation; chill on third day after confinement. Both tubes were greatly distended with pus; a small portion of the right ovary was not removed, owing to firm adhesions. Drainage for twenty-four hours. Patient menstruated regularly for several months, but has pain in the right ovarian region. February 10, 1887, reports feeling perfectly well, all pain has disappeared, and menstruation ceased.
	1886.												
11	March 6.	22	M.	3	....	B.	1 mo.	Yes.	No.	R.	Puerperal.	Cure.	Child born one month previous; patient had *no* pain; complains of profuse leucorrhœa; occasionally a gush of discharge came, which was followed by a cessation of leucorrhœa for some time. Bowels constipated; on defecation a pressing was experienced in the rectum, which caused an uneasy feeling in the lower part of the abdomen; both tubes were much distended; the uterus crowded upward and anterior. She complained also of a "very weak feeling;" night-sweats occasionally, and "creeping chills."
12	Nov. 17.	33	M.	3	4	L.	4 mos.	Yes.	Yes.	R.	Puerperal?	Not improved.	Was better for some time after operation, but complains now on the side from which the tube was not removed, so that frequently she is unable to work. The tube removed ruptured while separating the adhesions, and the pus escaped into the abdominal cavity.
13	Nov. 17.	28	M.	2	1	B.	2 yrs.	Yes.	Yes.	R.	Gonorrhœa.	Cure.	A small portion of the firmly adherent left ovary was not removed. Patient is perfectly free from pain and discomfort, menstruates regularly. (Seen April 7, 1890. She has ceased to menstruate nearly one year; feels perfectly well; has no reflex symptoms.)
14	Nov. 24.	18	M.	1	..	R.	5 mos.	Yes.	No.	R.	?	No improvement.	One year after operation she was said to be perfectly well. A report received recently stated that she was under treatment, from which I infer that she is ill, and hence report no improvement, although the attending physician gave me no description of her condition on request.
	1887.												
15	Jan. 13.	39	M.	6	1	B.	6 yrs.	Yes.	Yes.	R.	Gonorrhœa.	Cure.	The tissues were so friable that it was impossible to use a ligature, all hemorrhage was stopped with running catgut sutures. The adhesions were exceedingly dense and extensive. Her health is better now (two years after operation) than it has been for many years.
16	Jan. 23.	22	M.	....	....	B.	2 mos.	Yes.	No.	R.	Syphilis.	Cure.	Full report published in MEDICAL RECORD, August 20, 1887. Patient still has attacks of cerebral congestion about the menstrual period, but not as intense as formerly, otherwise perfectly well.
17	Jan. 31.	27	M.	....	3	R.	4 yrs.	Yes.	No.	R.	Puerperal.	Cure.	Had been unable for a long time previously to undergo any physical exertion on account of the intense pain produced in hypogastrium, right ovarian region, and back. Two years subsequently, condition good.
18	March 17.	36	M.	....	2	B.	13 yrs.	Yes.	No.	R.	Puerperal.	Cure.	Patient probably had an ordinary catarrhal salpingitis dating from her first abortion thirteen years ago, and from the time of the second recent abortion it changed to pyo-salpinx, her suffering becoming so intense that life was a burden to her.
19	March 24.	36	M.	4	2	L.	9 mos.	Yes.	No.	R.	Puerperal.	Cure.	Abscess of ovary, corresponding to the pyo-salpinx.
20	May 26.	30	M.	1	2	B.	13 yrs.	Yes.	No.	R.	Puerperal.	Improved.	Had syphilis several years ago.
21	June 12.	23	M.	1	....	B.	6 mos.	Yes.	No.	R.	Puerperal.	Cure.	Operated *after* rupture of the tube. See *American Journal of Obstetrics*, vol. xxii., No. 3.
22	June 19.	36	M.	2	2	B.	4 yrs.	Yes.	No.	R.	Puerperal.	Cure.	
23	June 24.	30	M.	....	....	B.	9 yrs.	Yes.	No.	R.	?	Cure.	One tube distended with pus, and the other with serum.
24	July 27.	29.	M.	....	1	B.	3 mos.	Slight	No.	R.	Puerperal.	Cure.	Operated after rupture of tube. See *American Journal of Obstetrics*, vol. xxii., No. 3.
25	Aug. 16.	25	M.	..	....	R.	4 yrs.	Yes.	No.	R.	Gonorrhœa.	Improved.	The left tube bound down by adhesions behind the uterus; tube enucleated and fastened with one catgut suture to the parietal peritoneum to prevent the appendage from sinking into its old bed from which it had been loosened, had healed over.
26	Sept. 5.	30	M.	....	....	B.	2 yrs.	Yes.	No.	R.	Gonorrhœa.	Cure.	

Laparotomies for Removal of Pyo-Salpinx.—Continued.

Number.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Both appendages or right or left removed.	Time of illness.	Adhesions.	Drainage.	Immediate result of operation: recovery or death.	Probable exciting cause of suppuration.	Ultimate result of operation on the condition of the patient.	Remarks.
	1887.												
27	Oct. 13.	28	M.	1	1	B.	.....	Yes.	No.	R.	Traumatic.	Cure.	Patient had a few days previous been curetted, and received intra-uterine treatment; since then had high temperature and chills; both tubes were greatly distended.
28	Oct. 29.	29	M.	....	....	B.	4 yrs.	No.	No.	R.	?	Cure.	The contents of tubes were muco-purulent and the muscularis much thickened.
29	Dec. 18.	28	M.	2	6	B.	3 mos.	Yes.	No.	R.	Puerperal.	Cure.	Illness dates from last abortion.
30	Dec. 21.	25	M.	3	....	B.	1 yr.	Yes.	No.	R.	Gonorrhœa.	Cure.	
31	Dec. 29.	29	M.	....	....	B.	8 yrs.	Yes.	No.	R.	Gonorrhœa.	Improved.	When seen in December, 1888, patient stated that she is improving from month to month.
32	Dec. 30.	19	M.	....	....	B.	8 mos.	Yes.	No.	R.	Gonorrhœa.	Cure.	The pains from which this patient suffered were unusually severe, probably due to the acuteness of the gonorrhœal infection; the husband having a very severe form of the disease.
	1888.												
33	Jan. 20.	39	M.	....	...	B.	11 yrs.	Yes.	No.	D.	Gonorrhœa.	.....	Patient took ether very badly; the tubes, unusually distended, ruptured during extirpation. Operation was hurried for the first reason. An oversight was also made by a faulty message to me, regarding the condition of patient, stating that the patient was doing well. However, the main error was in not putting a drainage-tube in from the begioning, as it was evident that the abdomen was not sufficiently washed out from the amount of pus which escaped into it. An ovarian hæmatoma was present.
34	Jan. 24.	36	M.	6	2	L.	6 yrs.	Yes.	No.	R.	Puerperal.	Improved.	
35	Jan. 27.	29	M.	1	....	B.	2 yrs.	Yes.	No.	R.	Puerperal.	Cure.	
36	Feb. 11.	24	M.	5	....	B.	3 yrs.	Yes.	No.	D.	Puerperal.	....	Complicated with a suppurating intraligamentous cyst, it and the tubes ruptured during enucleation, the pus escaping into the abdomen. She did not rally from the operation. Had lost very much in flesh and strength the last three months prior to operation.
37	Feb. 17.	30	M.	3	2	B.	3¼ yrs.	Yes.	No.	R.	Puerperal.	Cure.	
38	March 11	32	M.	4	....	R.	5 yrs.	Yes.	No.	R.	Puerperal.	Improved.	
39	March 29.	25	M.	1	....	B.	4 yrs.	Yes.	No.	R.	Gonorrhœa.	Cure.	
40	April 10.	33	M.	1	....	B.	7 yrs.	Yes.	No.	R.	Puerperal?	Cure.	
41	April 23.	20	S.	1	...	L.	1 yr.	Yes.	No.	R.	?	Cure.	
42	May 3.	32	M.	1	1	B.	5 yrs.	Yes.	No.	R.	Puerperal.	Cure.	
43	June 10.	35	M.	....	2	L.	2½ yrs.	Yes.	No.	R.	Gonorrhœa.	Not heard from.	
44	June 14.	28	W.	2	....	B.	3 mos.	Yes.	No.	D.	Gonorrhœa.	.....	Died second day. Septicæmia. Each tube contained at least 120 grammes pus, both ruptured during enucleation; the walls were *very* thin. Suspicion also of recent abortion.
45	June 19.	28	M.	....	....	R.	8 yrs.	Yes.	No.	R.	Gonorrhœa.	No improvement on *left* side.	Right side better.
46	June 28.	35	M.	4	1	B.	18 mos.	Yes.	No.	R.	Puerperal.	Cure.	
47	Nov. 30.	31	M.	1	....	B.	6 yrs.	Yes.	No.	R.	Gonorrhœa.	Cure.	Seen March 25, 1890. Patient is perfectly well since six months.
48	Dec. 17.	22	W.	1	1	B.	1 yr.	Yes.	No.	R.	Gonorrhœa.	Improved.	
	1889.												
49	Jan. 8.	17	M.	....	....	B.	18 mos.	Yes.	No.	R.	Gonorrhœa.	Improved.	Had been cohabiting since her fourteenth year, with numerous persons.
50	Jan. 22.	36	M.	2	1	B.	8 mos.	Yes.	No.	R.	Gonorrhœa.	Improved.	
51	Jan. 24.	26	M.	1	....	B.	5 yrs.	Yes.	No.	R.	Puerperal.	Improved.	Both tubes ruptured while separating the adhesions. Abscess of left ovary.
52	Feb. 11.	33	M.	5	....	B.	2 weeks.	Yes.	Yes.	R.	Puerperal.	Cured.	Acute salpingitis two weeks since delivery by midwife. Patient's temperature 103.4° to 105° F.; pulse, 130 to 140. Tubes contained about 180 grammes of pus; ruptured during enucleation. Drainage-tube removed on the sixth day. Patient had but little pain on examination—*none* otherwise
53	March 1.	c. 30	M.	...	....	L.	6 mos.	Yes.	No.	R.	?	Not heard from.	
54	March 20.	30	M.	6	....	L.	6 yrs.	Yes.	No.	R.	Puerperal.	Cured of her pains.	Has ventral hernia.
55	April 4.	26	M.	2	....	L.	6 yrs.	Yes.	No.	R.	Puerperal.	Improved.	Left tube greatly distended. Abscess of ovary as large as a fist. Adhesions very firm. The tube and ovarian abscess ruptured during enucleation.
56	May 16.	32	M.	2	1	B.	2 mos.	Yes.	No.	R.	Puerperal.	Cured.	Tubes contained about 200 grammes of thick greenish pus. Both ruptured during removal.
57	June 9.	38	M.	4	....	B.	14 yrs.	Yes.	No.	D.	Gonorrhœa.	....	The adhesions with sigmoid flexure were dense, and the gut surrounded with exudate, which accounted for the excessive constipation from which patient suffered. Its walls were in consequence very friable; the gut tore through while endeavoring to separate the adhesions. A portion was resected and the two ends brought together, first with interrupted sutures and then continuous suture of silk. Death from shock. Patient had regularly recurrent attacks of pelveo-peritonitis, and several attacks of general peritonitis.
58	June 18.	27	M.	3	1	B.	5 mos.	Yes.	Yes.	R.	Gonorrhœa.	Patient felt quite well when she left the hospital two months subsequent to operation. Has not been heard from since.	Complicated with an intra-ligamentous cyst. Hemorrhage from the torn adhesions so excessive that an intra-abdominal gauze packing was necessary. Drainage-tube left in four days. A severe *parotitis* developed after operation.
59	Aug. 23.	20	M.	....	...	L.	1 yr.	Yes.	No.	R.	Gonorrhœa.	Cure.	Patient has since the operation been free from pain so and is identical patient. Right pyo-salpinx was first removed on account of the intense pain from which the patient constantly suffered during the last three months. Previously she could bear the pain. The left tube seemed in good condition, it was consequently left; for the first few days the patient felt very well, but then began to complain of the opposite side—finally so much so that she was in constant agony; the adhesions changed perceptibly from one examination to the other (*i.e.*, twice per week), so that a second laparotomy became a matter of necessity. The tube was considerably distended with pus. Perfectly well when heard from four weeks ago
60	Sept. 11.	29	S.	....	....	R.	1 yr.	Yes.	No.	R.	?	.....	
61	Oct. 10.	29	S.	....	....	L.	.. ..	Yes.	No.	R.	?	)	
	1890.												
62	Jan. 15.	49	S.	....	....	B.	10 yrs.	Yes.	No.	R.	Gonorrhœa.		Relieved of old pain to some extent.
63	Jan. 17.	17½	S.	....	...	L.	1 yr.	Yes.	No.	R.	Gonorrhœa.	"	Felt perfectly well when she left hospital; not the slightest sign of former pain.
64	Jan. 28.	34	M.	2	....	B.	3 yrs.	Yes.	No.	R.	Gonorrhœa.		Feels much better than formerly.
65	Feb. 2.	29	M.	5	...	R.	7 yrs.	Yes.	No.	R.	Puerperal.	"	Feels much better than formerly.
66	Feb. 13.	32	M.	....	....	B.	12 yrs.	Yes.	No.	R.	Gonorrhœa.	"	Feels a little better than formerly.
67	Feb. 18.	43	M.	3	1	B.	2 yrs.	Yes.	No.	R.	?	"	Feels much better than formerly.
68	March 1.	39	M.	13	5	B.	20 days.	Yes.	No.	R.	Puerperal.	....	Felt perfectly well when she left hospital. Both tubes very much adherent to intestines; both ruptured during enucleation, and pus escaped in abdomen. Washed out and closed.

Laparotomies for Catarrhal Salpingitis.

Number.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Duration of illness.	One or both adnexa removed. Right or left.	Adhesions.	Drainage.	Immediate result of operation. Recovery or death.	Ultimate result of operation on the condition for which it was done.	Remarks.
	1884.											
1	Nov. 16.	36	M.	....	....	6 yrs.	B.	Yes.	Yes.	D.	....	Died on sixth day of peritonitis.
2	Nov. 30.	29	S.	1	....	4 yrs.	B.	Yes.	No.	R.	No improvement.	The cause of the non-improvement is perhaps due to the patient having become a morphine habitué, owing to the constant suffering which she endured.
	1885.											
3	Mar. 6.	30	M.	2	....	6 yrs.	L.	Yes.	No.	R.	Cure.	
4	April 24.	30	M.	3	2	7 mos.	L.	Yes.	No.	R.	Cure.	Ovary three times its normal size—abscess in centre. The pain in the left ovarian region was constant, no matter what treatment was used (due to the abscess).
5	Oct. 21.	32	M.	5	4	5 yrs.	L.	Yes.	No.	R.	Cure.	
6	Nov. 29.	28	S.	1	....	7 yrs.	R.	No.	No.	R.	None.	From the birth of child, seven years previously, she had constant pain in the right ovarian region, and suffered from epileptic seizures. The tube was much thickened and very sensitive; on several occasions during bimanual examination of the appendage, catalepsy was produced, and on two other occasions a true epileptic fit. For a short time after the operation she was free from the attacks, but they gradually returned, and are now more frequent and severer than formerly.
	1886.											
7	Feb. 12.	28	M.	3	....	6 mos.	R.	Yes.	No.	R.	Cure.	The same physical and psychical condition as in Case 6; only that the tube and ovary were bound down by perimetritic adhesions. No medication was used after operation. Reported last in December, 1888. Has not had a single epileptic seizure since operation, and the former excessive ovarian pain gradually diminished, and in between six and eight months after operation it had disappeared entirely.
8	June 28.	28	M.	2	....	7 yrs.	R.	Yes.	No.	R.	Improved.	When twenty-one years old she was infected by husband with gooorrhœa. The contents of tube were sero-purulent, the condition undergoing change to pyo-salpinx. The left tube seemed normal.
9	Sept. 13.	23	M.	1	....	2 yrs.	L.	Yes	No.	R.	Cure.	An ovarian hæmatoma also existed.
10	Dec. 29.	20	S.	....	....	3 yrs.	L.	No.	No.	R.	Cure.	Macroscopical appearances of the tube and ovary did not explain the cause of the intense suffering, though both were enlarged and ovary cystic; entirely free from adhesions. The specimen was unfortunately lost, so that a microscopical examinatoo could not be made.
	1887.											
11	Jan. 23.	35	M.	...	....	5 yrs.	L.	Yes.	No.	R.	Cure.	Ovary cirrhotic.
12	May 7.	30	M.	2	...	8 yrs.	L.	No.	No.	R.	Improved.	Small abscess in ovary, otherwise cystic degeneration. When last seen by me, about one year after operation, she was much improved. Report from family physician, however, received two weeks ago, states that she is entirely well now.
13	May 19.	27	M.	1	....	10 yrs.	B.	Yes.	No.	R.	Cure.	
14	June 11.	29	M.	....	....	4 yrs.	B.	Yes.	No.	R.	Improved.	
15	July 8.	26	M.	2	1	4 mos.	R.	Yes.	No.	R.	Cure.	Right ovarian abscess, size of a walnut.
16	July 12.	51	M.	3	....	2 yrs.	R.	No.	No.	R.	Cure.	A smooth mass, the size of a hen's egg, tender to touch, was felt to the right of the uterus; the much thickened tube could be felt going off from the uterus toward this mass, it was also very sensitive. The small tumor proved sarcoma of the ovary.
17	Aug. 22.	19	M.	....	1	6 mos.	R.	Yes.	No.	R.	Cure.	
18	Sept. 9.	27	M.	....	....	7 yrs.	B.	Yes.	No.	R.	Cure.	
19	Oct. 20.	31	M.	....	....	9 yrs.	L.	No.	No.	R.	Cure.	Patieot had been losing ouch blood at irregular intervals. The right adnexa had been removed by another operator. Tube-wall much hypertrophied. Sarcoma of the corresponding ovary size of a fowl's egg.
	1888.											
20	Feb. 10.	27	M.	....	....	2 yrs.	L.	Yes.	No.	R.	Improved.	
21	Feb. 13.	36	M.	1	1	16 yrs.	L.	Yes.	No.	R.	Cure.	Sigmoid flexure was torn half-way across in separating the adhesions. Lembert suture. Adhesions very extensive and firm.
22	May 19.	41	M.	4	3	3 yrs.	L.	Yes.	No.	R.	Cure.	
23	June 12.	39	M.	4	....	17 yrs.	B.	Yes.	No.	R.	Improved.	
	1889.											
24	Feb. 16.	32	M.	1	....	13 yrs.	B.	Yes.	No.	R.	Cure.	Patient during the last seven years of her illness was never without pain; half of the time she was unable to do anything on account of recurring attacks of pelveo-peritonitis. Excessive metrorrhagia. She has since operation been entirely free from pain, and says that she has not felt so well for fourteen years as now.

Laparotomies for Tubercular Salpingitis.

Number.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Duration of illness.	One or both adnexa removed. Right or left.	Adhesions.	Drainage.	Immediate result of operation. Recovery or death.	Ultimate result of operation on the condition for which it was done.	Remarks.
	1888.											
1	Feb. 11.	38	M.	.....	.....	.....	R.	Yes.	No.	R.	Cure of pain and bleeding.	Symptoms were constant pain on the right side, and profuse hemorrhage. Congenital absence of the left appendage. Am ioformed that patient has since died of pulmonary tuberculosis. (Both tube and ovary were tubercular.)
	1890.											
2	Feb. 7.	23	M.	....	.....	7 mos.	B.	Yes.	No.	R.	Under observation. Cure of the former pains.	Patient felt well until seven months ago, when pains began in the left ovarian region, which gradually increased in severity and spread over the entire abdomen, at the same time profuse metrorrhagia was present. This was benefited by local treatment in another hospital the pains, however, continued. On admission into the hospital, the general condition of the patient was poor; anæmic, had lost flesh; elevation of temperature, 99.8° F. in axilla; diarrhœa. The uterus firmly fixed by a large mass on the left side, with irregular boundaries, quite firm to touch, pushing the uterus upward and forward; a similar mass on the right side, but not so large. The masses felt proved to be the tubes and ovaries, studded with tubercles and surrounded by an exudation material, which was encapsulated. The uterus was separated from the rest of the upper part of the abdominal cavity by a thick membrane, which formed a roof, this and the adherent intestines were thickly studded with tubercles; there was very little ascitic fluid present. The peritonitis was undoubtedly secondary, the tubercular salpingitis the primary affection.

Laparotomies for the Removal of the Uterine Appendages, not the Seat of Markea Disease.

Number.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Duration of illness.	Condition for which the operation was done.	One or both appendages removed.	Adhesions.	Drainage.	Immediate result of operation, Recovery or death.	Ultimate effect of operation on the condition for which it was done.	Remarks.
	1885.												
1	Jan. 3.	24	M.	....	2	2 yrs.	Large interstitial fibroid.	B.	Yes.	No.	R.	Cure.	Was seen two years subsequent to operation, when the tumor had decreased fully three-fourths of its original size. Hemorrhage, which was before operation very profuse, had ceased entirely.
	March 7.	24	M.	....	..	9 yrs.	Hystero-epilepsy.	B.	No.	No.	R.	Improved.	The disease began soon after the appearance of menstruation; attacks frequent and very severe about the menstrual period. In the beginning no change was noticed from the operation. Information received from an acquaintance, December 5, 1888, states that the attacks lately became diminished in frequency and severity; the improvement being more marked from month to month.
3	1886. March 17.	48	M.	3	....	5 yrs.	Large fibroid, causing pain and hemorrhage.	B.	Yes.	No.	R.	Hemorrhage and pain ceased.	
4	1887. Aug. 26.	30	M.	....	....	....	Interstitial fibroid, causing pain and hemorrhage.	B.	Yes.	No.	R.	Bleeding and pain ceased.	
5	Sept 2.	35	M.	3	...	1 yr.	Interstitial fibroid causing pain and hemorrhage.	B.	Yes.	No.	R.	Cure. (?)	Bleeding and pain had ceased when patient left hospital. Have been unable to trace her since.
6	1888. May 14.	17	S.	....	....	4 yrs.	Hystero-epilepsy from time menses began.	B.	No.	No.	R.	None.	Both tubes and ovaries were prolapsed. Epileptic and cataleptic seizures were most severe and frequent about the menstrual period, and seemed to take their origin from the appendages. Numerous times, in the clinic and hospital, an attack was brought on by pressing either one of the ovaries during bimanual examination. For six months subsequent to operation she was entirely well, so that a permanent cure was thought of, but then the attacks gradually returned again, and are now, from last report, as severe as ever.
7	June 14.	38	M.	..	....	Several years.	Hystero-epilepsy.	B.	Yes.	No.	R.	None.	
8	June 28.	29	S.	....	....	6 yrs.	Interstitial fibroid.	B.	Yes.	No.	R.	Hemorrhage and pain stopped.	
9	July 10.	26	M.	....	....	1 yr.	Constant hemorrhage.	B.	No.	No.	R.	Cure.	Patient had undergone every imaginable form of treatment, in my care and at the hands of other physicians, without benefit; finally her physician sent her back to me for operation. She had wasted to a mere skeleton from a former moderately corpulent woman.

Laparotomies for Hydro- and Hæmato-Salpinx.

Number.	Date of operation.	Age.	Married or single.	Number of children.	Number of abortions.	Time of illness.	One or both adnexa removed.	Hydro- or Hæmato-Salpinx.	Adhesions.	Drainage.	Immediate result of operation, Recovery or death.	Ultimate result of the operation on the condition of the patient.	Remarks.
	1885.												
1	Jan. 17.	28	M.	...	....	5 yrs.	B.	Hydro-salpinx.	Yes.	No.	R.	Cure.	
2	Jan. 29.	43	M.	10	....	3 mos.	R.	Hæmato-salpinx.	Yes.	Yes.	R.	Cure.	Had retro-uterine hæmatocele and beginning peritonitis; it was on account of the latter that the operation was done without delay. Drainage-tube removed on the ninth day.
	1886.												
3	Nov. 30.	27	M.	....	....	6 yrs.	R.	Hydro-salpinx.	Yes.	Yes.	R.	Not improved.	
4	Dec. 30.	24	M.	....	1	4 yrs.	R.	Hydro-salpinx.	Yes.	No.	R.	Cure.	Had a severe attack of general peritonitis subsequent to operation, due probably to eventration of intestines, which became necessary to find the source of a profuse hemorrhage occurring during operation.
	1887.												
5	Jan. 23.	30	M	...	...	6 yrs.	L.	Hydro-salpinx.	Yes.	No.	R.	Cure.	
6	July 14.	28	M	2	....	1 yr.	B.	Double hydro-salpinx.	Yes.	No.	R.	Not improved.	A portion of the right ovary was not removed, owing to very dense adhesions; from this remnant subsequently an ovarian cyst arose, which necessitated another laparotomy.
7	Nov 8.	29	M.	1	1	2 yrs.	L.	Hydro-salpinx.	No.	No.	R.	Cure.	
	1888.												
8	March 6.	21	S.	....	....	?	B.	Hydro-salpinx.	Yes.	No.	R.	Not improved.	
9	May 6.	28	M.	1	1	4 yrs.	R.	Hydro-salpinx.	Yes.	No.	R.	Cure.	

Three cases of removal of the appendages for other conditions, viz., two tubal pregnancy, and one ovarian hæmatoma which had ruptured and produced peritonitis from the blood effused in the abdomen, are not enumerated in this table. These cases also recovered.

Special attention is called to cases Nos. 10, 11, 18, 25, 27, 52, 56, 57, 58, and 68 of operations for pyo-salpinx, and Nos. 6, 7, 16, 19, and 21, for catarrhal salpingitis. Also to the cases where the appendages were removed for fibro-myomata. Case 60 is first noted as "no effect;" the same case 61 is marked "cured" after removal of the other tube; as per last report from the patient.

If no symptoms occur within two or three months after an abortion or confinement, and no history of infection can be elicited or gonococci found in the vaginal secretions, the case is classed as "cause unknown."

To make a short résumé of the principal part of the table, we have the following:

Not improved by the operation	10	patients.
Improved by the operation	24	"
Cured by the operation	58	"
Not heard from, or insufficient elapse of time since operation	11	"
Died from the result of operation	8	"
Case 60 and 61 enumerated under one head	1	"
Total	112	"

Pyo-salpinx.

Class A. Both adnexa removed for gonorrhœal pyo-salpinx ..... 16 times.
Class B. Right adnexa removed for gonorrhœal pyo-salpinx..... 2 "
Class C. Left adnexa removed for gonorrhœal pyo-salpinx..... 2 "

Division 1. 3 cases had symptoms less than one year.
" 2. 7 " " " one to three years.
" 3. 1 " " " from three to five years.
" 4. 5 " " " more than five years.

In Division 1, there was 1 positive cure; 1 not heard from, but felt well when last seen; 1 perfectly relieved of former symptoms, yet the time since operation is too short to give a definite report. In Division 2, there were 4 cases positive and complete cure, 3 cases improvement. In Division 3, there was 1 case complete cure. In Division 4, there were 2 cases complete cure. 3 cases improvement.

Class B. 1. One patient had symptoms between three and five years.
2. " " " " more than five years.
1st. Improved. 2d. No effect was produced.
Class C. Two patients had symptoms between one and three years. One cure. One improvement when last seen.

From patients in whom the pyo-salpinx seemed to arise in connection with a confinement or an abortion:

Class A. Both adnexa ..... 19 times.
" B. Right adnexa only ..... 2 "
" C. Left adnexa only..... 7 "

In Class A: In 9 cases the disease dated less than one year; these were all cured. In 2 cases the disease dated between one and three years; both cured. In 4 cases the disease dated between three and five years; among them we note two complete cures, and two improvements. In 3 cases the disease lasted more than five years; two cures, and one improvement.

In Class B: There was 1 case between three and five years, and 1 case more than five years; both improved.

In Class C: Three times less than one year: 1 no effect, one cure, and one not heard from. Once between one and three years; cure. Once between three and five years; improvement. Twice more than five years; one improvement. one cure.

The double pyo-salpinx was due, once to syphilis; one complete cure; its duration was less than one year. A right pyo-salpinx, due to syphilis. Between one and three years' duration, once, with no improvement. One left syphilitic pyo-salpinx; improvement.

Of no definite origin we note: Double pyo-salpinx, three times. Duration between one and three years, once; improvement. Duration between three and five years, once; cure. Duration more than five years, once; cure.

Right side, twice. Once, less than one year; no improvement. Once, between one and three years; no improvement.

The left tube is noted three times. Once, less than one year duration; cure. Twice, between one and three years; both cured.

On fibro-myomata, provided the neoplasm is interstitial and has not undergone any degenerative changes, or is not tightly impacted in the pelvis, the operation has invariably a good result; it is different, however, in cases of severe affections of the nervous system, as can already be seen by the few cases tabulated by me.

I believe, also, that the majority of those cases of catarrhal salpingitis which are so exceedingly obstinate, and in which the symptoms will but temporarily improve, can be traced to specific infection.

It may not be amiss here to make a note as to the frequency of gynecological patients suffering with some form of salpingitis. For this research I am indebted to my assistant, Dr. C. J. Musgrave, who kindly reviewed my history books for this purpose. Five thousand cases were taken without selection:

Ages.	Both.	Right.	Left.	Total number in each division.
Under 20.....	12	—	4	16
20 to 25.....	117	22	17	156
26 " 30.....	183	22	20	225
31 " 35.....	26	9	8	43
36 " 40.....	17	5	8	30
41 " 45.....	—	1	3	4
46 " 50.....	1	1	—	2
Over 50.....	—	1	—	1
Total.....	356	61	60	477

In one hundred cases seen only in consultation, the percentage is much greater:

Left appendage:

Under 20 years..... 1 case.
Between 20 and 25 years..... 1 "
" 26 " 30 " ..... 2 cases.
" 31 " 35 " ..... 6 "
Total..... 10 "

Right appendage:

Between 31 and 35 years ..... 6 cases.

Both adnexa:

Between 20 and 25 years..... 7 cases.
" 26 " 30 " ..... 6 "
" 31 " 35 " ..... 3 "
" 36 " 40 " ..... 1 "
" 41 " 45 " ..... 1 "
Total..... 18 "

Making a total of 34 patients, out of 100 patients seen by me with regard to diagnosis, who were affected with inflammation of the uterine adnexa.

We also notice in our observations that the salpingitis was never primary. A. Martin, from an analysis of 287 cases of tubal disease, has made a similar observation.[1]

Do not for a moment think that I want to see the various other remedies used in diseases of the uterine appendages supplanted by the knife; nay, on the contrary, I uphold conservatism, and am a strong advocate for the use of massage, electricity, etc.; but I cannot stand by and allow this or that one to put on claims for a certain mode of treatment and decry the surgeon's knife, irrespective of the etiological factor and the pathological state of the disease. My conscience, and the duty we owe to the public at large, will not allow me to become one-sided and unscientific, nor permit enthusiastic reports to go among the members of our profession, without giving a word of caution when my experience and judgment dictate it. We are physicians, not charlatans who cure cancer with salves, and consumption by faith; and as physicians let us be broad and eclectic in our treatment of disease.

THE TRUE RELATION OF DISEASED CONDITIONS IN THE UPPER AIR-PASSAGES TO THE SO-CALLED NASAL REFLEXES.[2]

By F. H. BOSWORTH, M.D.,
NEW YORK.

WHILE glancing through some old medical books a few evenings since, I came upon the following passage from the writings of that "learned and renowned doctor," Lazarus Riverius:[3]

> "That Rheum is called Catarrhus which doth fall
> Upon the Breast, upon the Jaws we call
> It Branchus, Coryza through the Nose doth fall."

"When the humor flows upon the Breast, the disease keeps the general name of a Catarrh or Defluxion; when it falls upon the Jaws, and Aspera Arteria or rough Arteries, it is called Branchus, Raucedo, or Hoarseness; when it flows into the Nostrils it causeth not only a Coryza or Murrh, but Ozæna or Polypus. But in other parts it pro-

[1] Zeitschrift für Geburtsheilkunde und Gynäkologie, vol. xiii., p. 300.
[2] Read before the New York Academy of Medicine, May 1, 1890.
[3] Culpeper's translation, London, 1678, p. 52.

duceth various effects; if it fall upon the Nerves, it produceth a Torpor or Numbness, a Palsie, Convulsion, Trembling; if in the Ears, Deafness, Swelling; if in the Eyes, Ophthalmy or Inflammation, Tears, Blindness; if upon the Uvula or Palate, Swelling, Looseness, or Laxity, or Ulcer; if in the Throat, the Quinzy; if on the Lungs, the Pleurisie, Inflammation, or Imposthumation, Cough, Shortness of Breath, Spitting of bloud, Consumption; if into the Stomach, Vomiting, Want of appetite; if into the Bowels, it causeth Diarrhœa and Dysentery; therefore it is rightly conceived that the greatest part of diseases that trouble Man's body have their original from the Head."

This is the result of the studies of a very keen observer, who practised general medicine, be it remembered, and was not a specialist, some two hundred and fifty years ago; and I bring forward this quotation to-night, as possessing a somewhat curious interest, and as showing that the idea that all diseases come from the nasal passages, or the head, as Riverius terms it, is by no means a new one. I am not, however, disposed to go quite so far as our ancient friend, for I am not one of those who believe that the nose is absolutely the direct cause of the large number of diseases which are now recorded in the category of nasal reflexes. Furthermore, I think it still an open question whether these diseases, when met with in connection with intranasal disorders, should properly be classed as reflexes. This term is an exceedingly vague and indefinite one, which we use oftentimes to explain certain symptomatic manifestations, when the real connection between the primary disease and the irregular or unusual manifestation is obscure and hidden. Certainly many of the affections which we are accustomed to term as reflex, I think, properly must be regarded as directly symptomatic.

Thus, for instance, we not infrequently hear cough spoken of as a reflex disturbance due to disease of the nose or naso-pharynx. A cough, in these cases, is purely a symptom of a secondary complication of a catarrhal nature in the larynx or trachea, due directly to the disease in the parts above. Frontal headache is oftentimes spoken of as a reflex disturbance due to intranasal disease. In certainly many instances a frontal headache can be better explained by regarding it as due to the fact that the turgescent condition of the blood-vessels of the nasal cavity exercises a certain amount of pressure on the terminal filaments of the first branch of the fifth pair of nerves. Epiphora is often spoken of as due to reflex disturbance from intranasal disease. This is unquestionably to be explained by the fact that the catarrhal inflammation of the nasal mucous membrane extends into the lachrymal sac, producing occlusion. A still further extension of the inflammation may result in involving the conjunctiva in an inflammatory process, which is in no way to be regarded as a reflex result.

I bring forward these points, simply to illustrate what I regard as, to a certain extent, a misuse of the term "reflex."

The main interest in the discussion to-night, as far as I am asked to take part in it, concerns, I believe, the question of hay-fever and asthma. I have already written at considerable length on this subject, and therefore shall be somewhat brief in what I have to say to-night, for fear of repeating what has been already said.

I do not believe that intranasal disease is the cause of every case of asthma, or of every case of hay-fever. As far as I remember, I have never made any direct statement to this effect, although the tone of the discussion at the last meeting of the Society (in which I was quoted and referred to) seemed to point in that direction. My position in this matter is based on a pretty large observation of both hay-asthma and perennial asthma, as it has manifested itself in the somewhat large number of patients which have been under my personal care, and is the direct teaching of the clinical histories of these cases, and especially of the results of treatment. My position, briefly stated, is as follows:

1st. The special morbid lesion which gives rise to a paroxysm of perennial asthma is a dilatation of the blood-vessels which circulate in the mucous membrane lining the bronchial tubes, the result of a vaso-motor paresis. This vaso-motor paresis differs from inflammation in that, while constituting apparently its first stage, it shows no tendency to go further. Muscular spasm, therefore, according to the old teaching, plays no part whatever in producing an asthmatic attack.

2d. There are two predisposing causes of asthma. First, that condition of the general system which we call neurosis, under the influence of which an individual becomes liable to vaso-motor disturbances in one portion of the body or another. This I regard is as good a definition, from a pathological point of view, as we can give of what we call neurosis. I can only say that, as far as clinical observation teaches us, the one pathological lesion which characterizes the direct manifestation of a neurosis is a vaso-motor paresis in one portion of the body or another. In asthmatics this vaso-motor paresis involves the blood-vessels which circulate in the mucous membrane of the bronchial tubes. The second predisposing cause of asthma is a chronic inflammatory process involving some portion of the upper air-tract. In all chronic inflammation the prominent feature is vascular dilatation. The whole mucous membrane of the upper air-tract is very closely and intimately related, one part being in quick and close sympathy with another. A hyperæmia of the blood-vessels of the nose shows a marked tendency to be followed by a similar condition of the mucous membrane of the bronchial tubes. This, I think, is necessarily a corollary of what we now recognize as the great respiratory function of the nasal passages, by which the temperature and moisture of the inspired air is nicely regulated and adjusted before its entrance into the bronchial tubes.

If I have made clear these two propositions of what a neurosis is, and of how closely related the two portions of the respiratory tract are to one another, I think the dependence of an asthma on a nasal condition can be clearly understood.

Asthma, as I said before, is not in all cases caused by an intranasal condition, but an intranasal morbid condition plays an exceedingly important part in its development. Given an individual with hypertrophic rhinitis, or any other obstructive lesion in the nasal cavity, who, at the same time, is of a well-marked neurotic habit, and I think you have a subject who presents exceedingly favorable conditions for the development of an asthma; especially if the nasal condition in this individual has existed for a sufficient length of time as to have developed a mild tracheal or bronchial catarrh. On the other hand, take an individual of a mild neurotic habit, with healthy air-passages; or, again, an individual of a notably phlegmatic temperament, with a very advanced condition of chronic inflammation in his nasal passages, and the development of an asthma would be a most curious phenomenon, according to my views and observation.

I hold firmly, therefore, to the opinion that in a diseased condition of the nasal cavities, of a chronic inflammatory character, or of an obstructive character, we have a powerful predisposing cause of asthma. I go no further than this, and, as far as I remember, I never have made a statement which could be interpreted as meaning more than this. Dr. Robinson, I think, in the discussion at the last meeting, does me something of an injustice when he quotes me as saying that I have "never known a case of asthma to occur in other than an obstructive lesion of the nose or upper air-passages." In my original paper, "Asthma, with an Analysis of Eighty Cases,"[1] I made the assertion that "a large majority, if not all, cases of asthma were dependent upon some obstructive lesion in the nasal cavity." In a later publication I made the assertion that the lesion in the nasal cavity was always of an obstructive character. The way in which Dr. Robinson quotes me,

[1] American Journal of the Medical Sciences, September, 1888.

I think, is a trifle misleading, as one would infer that I made the somewhat extravagant claim that no case of asthma could occur without an obstructive lesion in the nose. I simply say that I believe a large majority of cases are dependent upon an intranasal lesion, and when such lesion exists it is obstructive. I have never seen a case of asthma in atrophic rhinitis, and should consider it a most curious phenomenon if such were to present itself.

When I say that asthma is dependent on nasal disorders I do not say that all cases are caused by it. I assert merely that there is a close relation, and this is evidenced by the report that I previously made, in a manner that cannot be questioned. Of the eighty cases reported the treatment was largely intranasal. Of these cases forty-six were cured, twenty-six were improved. Now, I possibly may have been carried away by a certain degree of enthusiasm in reporting these cases. I take it, few of us, in endeavoring to establish a somewhat novel premise, are capable of making our reports without a certain degree of bias. In my eighty cases I endeavored certainly to make my reports with fairness and candor, and the results were obtained by a somewhat extensive correspondence with the patients who had passed out of my observation, and none were reported, as far as I know, who had not responded to my letters or had been personally seen. Now, if in eighty cases forty-six can be cured and twenty-six improved by the local treatment of the nose, there can be no question that we have established the fact, to my mind beyond controverting, that a very large majority of cases, if not all, are dependent upon an intranasal lesion; and by this dependence I do not mean caused by, but that the two affections are so closely related that the asthma can be very materially affected and controlled by medication to the nose. This fact certainly has been established by numberless observations. If a paroxysm of asthma can be arrested by an application of cocaine in the nose, as I have seen it over and over again, the relationship between the nose and the bronchial tubes is clearly established and without question. If this can be done in a large number of cases, this relationship is demonstrated to be still more intimate. If the permanent control of a chronic inflammation of the nasal mucous membrane cures asthma, we have not only shown this relationship in a very clear manner, but we have presented to the profession a method of treating asthma which is not only definite and certain in its action, but most satisfactory, in that the treatment is directly under our eye, and what we accomplish can be seen and observed. In other words, in place of a somewhat obscure pathological condition, there are presented certain physical manifestations which are under ocular inspection, and the treatment of which also is under ocular inspection, and our success is carefully estimated by the physical improvement in local conditions which we observe from day to day.

As regards hay-fever; this I consider as practically one and the same disease with asthma, and to be treated in the same way. On this point I have already written so much at length that I do not feel at liberty to repeat it here.

One word as regards certain nervous diseases which have been classed among the nasal reflexes. I refer especially to chorea and epilepsy. I have seen nothing in my own practice which warranted me in the belief that epilepsy should be regarded as a nasal reflex, although I do believe that an intranasal condition is capable of proving a marked source of irritation in many of the nervous affections, and that an epilepsy may be aggravated by an intranasal morbid lesion, the removal of which may to a certain extent modify the appearance of the convulsions. That an epilepsy has ever been cured by intranasal treatment, I think, is open to very serious question. The only instance of this kind I recall is that of Roe, read at the last meeting of the State Medical Society. I am disposed, however, to think that it is too early to definitely estimate the results in this case.

Of chorea, I have seen a number of instances. Only three, however, have been sufficiently long under my care to warrant my giving a definite opinion concerning them. One of these was a young lady from Havana, aged twenty, with chorea of the larynx, which was characterized by the most distressing bark, perhaps, that I have ever listened to in my office. Dr. Starr saw this case in consultation, and will readily recall it. She was entirely cured by intranasal treatment, and now, at the end of nearly two years, has had no recurrence. Another case was that of a boy, aged seventeen, referred to me by Dr. Janvrin, with hypertrophic rhinitis and deformed septum, in connection with which there was well-marked choreic movements, which disappeared permanently on the relief of the intranasal condition. A third case is a young man, aged sixteen, still under treatment. This was a marked case of chorea, and rather a distressing one. The improvement, however, has been fairly satisfactory, and I am disposed to anticipate an entire relief, if the young man persists in his treatment. Dr. Loomis saw this case a few weeks ago, and, as I understand it, gave an absolutely unfavorable prognosis. I hope yet to convince Dr. Loomis that this unfavorable opinion was premature.

I do not mean to suggest any especial connection here, reflex or otherwise, between chorea and disease of the upper air-passages, for I do not claim any such connection to exist. The improvement in these cases is to be explained by the fact that the removal of morbid conditions in the air-passages of young patients is often followed by marked improvement in the general health. In other words, I consider the successful treatment of catarrhal disorders in the young as one of the very best of tonics. This, I take it, is the prominent indication for treatment in chorea.

Before closing, may I add one word in regard to a criticism which Dr. Robinson makes on my recent volume on "Diseases of the Nose and Naso-pharynx," wherein he says that, on page 525, the statement is made that "the secretion from the nasal passages of the pharynx never makes its way into the laryngeal cavity under any circumstances." Comparing this with the passage on page 550 of the same volume, he claims an inconsistency, in that I make the assertion that "cough is present in certain cases, especially if there is much secretion which has made its way down the pharynx into the larynx, exciting laryngitis."

The quotation from page 525 is from the article on naso-pharyngeal catarrh; while that on page 550 is in the article on adenoid disease of the naso-pharynx. In the former case the disease is one of adult life, in which I do not believe the secretions ever make their way into the larynx; in the latter instance I was discussing a disease of child life, wherein the cough may unquestionably be due to the secretions making their way into the larynx.

I consider myself guiltless of any inconsistency whatever in the statements, and see no reason to change the views there expressed. These points are scarcely germane to the subject under discussion, but since Dr. Robinson has, in rather an elaborate manner, brought them in, I think I am entitled to equal prominence in correcting his somewhat unnecessary charge of inconsistency.

I think the weight of his charge, however, is more than overbalanced by the compliment he pays me, in that the detection of this so-called inconsistency shows conclusively that Dr. Robinson has given my work a most careful reading. I can only trust that this may eventually inure to his great profit.

Nitrite of Amyl is commended as the most rational and successful antidote to use where chloroform or cocaine seems to threaten life by their unfavorable action on the heart. A few drops of nitrite of amyl, administered by inhalation, will be one of the most probable means of restoring the heart's action.—*Journal of the American Medical Association.*

RUMINATION IN MAN.[1]

By MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY, NEW YORK.

By rumination, or "chewing the cud," we designate a condition in which the food returns, without nausea, in small portions, from the stomach through the œsophagus into the mouth, some time after meals; here it is chewed anew and swallowed.

Rumination belongs to the normal physiological processes of most herbivora, and forms the most marked characteristic of the whole class of mammals which we call "ruminants."

Here the rumination is a most appropriate arrangement. The herbivorous animals are obliged to partake of great quantities of food, as the nourishing value of the grasses is relatively a small one. On the pasture they must make use of their time for gathering and swallowing the grass. Afterward, when they have more time and leisure, they reduce the food to smaller particles and mingle the same with saliva, by the act of rumination.

In view of this circumstance the stomach of ruminating animals differs in construction from that of other animal classes. It consists of four compartments: Paunch, or rumen, honeycomb-bag, or bonnet, manyplies, or psalter, and reed, or rennet. The first two serve more or less as reservoirs, whereas the two latter contain the glandular elements for digestion.

At the first act of swallowing, the food materials enter the rumen and the bonnet, whereas after chewing the cud the food passes directly into the psalter and rennet.

Chewing of the cud, which is so very important and appropriate for the whole class of ruminants, occurs, though quite rarely, in man, and is designated then as rumination or merycism.

For man rumination is unnecessary, and more or less a hindrance. One can hardly define rumination as a disease, for the bodily functions are in no way harmed by that process, but as an abnormal, anomalous condition, which must be socially an uncomfortable and disagreeable burden to its owner.

As I have lately had the opportunity to observe two cases of rumination in man, I take the liberty to-night of speaking more fully on this interesting subject.

1. **History of Rumination.**—In ancient times there were confused views on rumination in animals which in fact do not ruminate at all. Thus Aristotle and Plinius[2] speak of ruminant hares and hamsters. The occurrence of rumination in man, however, is not mentioned.

Fabricius ab Aquapendente,[3] in 1618, first observed and described two cases of typical rumination in man. The physicians of that time imagined that the stomach of ruminating men divided itself into as many divisions as that of ruminating animals. But Fabricius ab Aquapendente had the opportunity of making the autopsy after the death of his ruminants, and could state in this way that that conjecture was not correct. Fabricius found the stomach only dilated and thickened, but otherwise not different from any other stomach of man.

At this time there were many mystic ideas about the origin of rumination; it was believed, for instance, that the merycists descended from horned parents. Thus, as the father of his ruminating subject was believed to have had a horn on his forehead, Fabricius[4] remarks: "Ex quo forte datur nobis intelligi parentis semen aliquam habuisse affinitatem cum cornigeris animalibus, neque mirum fuisse genitum filium simile quid a parente contraxisse."

A little while afterward, imitation was supposed to be the main cause of rumination. It was generally assumed that all ruminants had been suckled in their infancy by ruminant animals, and in this way had learned from their feeding mothers the process of rumination.

With Peyer,[1] who, in 1685, had reported twelve cases of rumination in man, begins the scientific discussion of this subject. The same is connected with the doctrine of rumination in general.

2. **Mechanism of Rumination in Animals.**—The act of rumination is composed of: Ejaculation (forwarding the bolus from the stomach through the œsophagus into the mouth), chewing, and swallowing. The main difficulty of the mechanism lies in the explanation of the ejaculation, which act is equally important for rumination as well as for vomiting.

Peyer supposed that the rumen contracts, and in that way causes the food to come up. In man, also, Peyer attributed rumination to abnormal contractions of the stomach. Daubenton[2] attributed the act of preparing and forming the returning bolus for rumination to the bonnet. Flourens[3] made the resection of the bonnet in a sheep, but on the day following the operation the sheep began to ruminate again in the usual manner. Flourens therefore rightly concluded that the bonnet cannot be the causing moment of rumination. Flourens now ascribed this part of forming the bolus to the lower part of the œsophagus, to the "gouttière œsophagienne;" he compares the same with "an open hand, which takes the grasses and contracts, in order to push them thereafter into the œsophagus."

Colin[4] experimentally refuted Flourens's theory; according to Colin, the forming of the boli is not of much consequence. The substances undergoing rumination are pushed by the contractions of the rumen and the bonnet, aided by the work of the diaphragm and of the abdominal muscles, into the infundibulum of the œsophagus. "The œsophagus seems to become relaxed now, dilates, and makes room for the entering food substances; thereafter it closes and exerts an antiperistaltic contraction, by which way the contents come into the mouth."

Lately the following theory for the mechanism of rumination has been advanced by Chauveau and Toussaint.[5] In the moment of ejaculation or rejection, the glottis closes, the diaphragm quickly and vigorously contracts; thereby a considerable rarefaction of the air contained in the thoracic cavity arises, and in the meantime a diminution of pressure. The œsophageal tract is now under negative pressure, and in this way pumps a portion of the bonnet-contents; which portion hereafter is carried into the mouth by an antiperistaltic movement of the œsophagus.

This doctrine of the mechanism has been fully approved by the experiments of Luchsinger,[6] made on morphinized goats, in which the stomach and the glottis have been exposed by operation in such a way that the whole process of rumination could be quickly and plainly observed.

These experiments showed also that any irritation of the rumen (slight pressure, pouring of warm water, tetanizing currents) gave rise to rumination. Thus Luchsinger concludes that rumination is a reflex process. As there is no rumination, according to Flourens, after the nervi vagi have been cut through, Luchsinger deems it probable that the centre of rumination is located in the medulla oblongata, and that transmission passes by way of the vagus.

3. **Anatomy.**—Upon the different ideas of the mechanism of rumination in animals depend the conjectures which have been made upon anatomical anomalies of ruminating men.

Flourens's theory made the idea probable that the lower part of the œsophagus must be dilated. Thus, indeed,

Arnold [1] and Luschka [2] have found, in autopsies made on ruminating men, the lower part of the œsophagus dilated in a high degree; at the top of this dilatation there was recognizable a slight constriction. Arnold designated this part as "Vormagen" (ante-stomach), and Luschka as "antrum cardiacum." Both of them ascribed rumination to this anatomical anomaly. Besides, both of them found, in their autopsies of ruminants, the interior branch of the nervus accessorius Willisii to be as thick and well developed as the exterior branch, whereas usually it is only half as thick.

But Poensgen [3] showed that the antrum cardiacum cannot be made responsible for rumination. Among five stomachs of healthy grown people he found the antrum cardiacum present twice. Koerner [4] also found the antrum cardiacum present in eight out of twenty-two normal stomachs.

As regards the thickness of the interior branch of the nervus accessorius Willisii, the same varies very much, according to Cruveilhier, even in non-ruminating people.

In harmony with Toussaint's theory, the belief in a deficient closure of the cardia as a cause of rumination would be perfectly justifiable. Already, in 1859, And. Dumur [5] suggested that mérycisme is a neurosis, effected by a sometimes incomplete paresis of the cardiac portion of the stomach. The movements of the stomach being directed from the pylorus to the cardia, a portion of the stomach-contents enters through the relaxed cardia into the lower part of the œsophagus, and by exciting antiperistaltic movements comes into the mouth.

This conjecture, to consider rumination as a neurosis of the stomach, with relaxation of the cardia, has been more generally accepted within late years. Koerner, Poensgen, Johannessen, Alt, Boas, Ewald, coincide in this view. Several of the authors mention in their ruminating cases the presence of Meltzer's "Durchspritzgeraeusch" (the sound which appears immediately after swallowing water at the processus xyphoides), which should prove the relaxation of the cardia.

Alt's [6] patient swallowed two small gold-fish, and, when ruminating, they returned alive. Alt urged that the cardia must have been deficiently closed, for otherwise the fish could not very well have passed that spot without being compressed and killed.

But even this point—a relaxation of the cardia—does not seem to be always found constant. Boas [7] found in his case of rumination a normal "Durchpressgeraeusch" (the soun which is heard at the processus xyphoides seven seconds after swallowing water), and I, likewise, could observe the same phenomenon in my two cases, which will be reported later.

Some of the authors suggest a too firm closure of the pylorus as an aiding cause of rumination; among them Alt. The food not being able to pass through the closed pylorus would remain longer in the stomach and would cause the same to eject its contents upward, which process is the more easily done in these cases, as the cardia is relaxed.

The fact is, that the stomach has often been found enlarged in merycists, but it is still quite questionable whether we could say here, "post hoc ergo propter hoc." Any other palpable anatomical alteration, as being in connection or the cause of rumination, must at present be excluded.

4. **Etiology.**—Should we not accept an anatomical alteration in the upper digestive tract, in its nervous or central apparatus—which supposition is in no way proven or even made probable, as we have seen above—as the cause of rumination, there remain yet two possibilities for the origin of this anomaly, namely, heredity and self-acquisition. But as heredity was met with only in very few cases of rumination, and thus cannot be taken for the main cause of the affection, it appears of importance to lay most stress on self-acquisition.

The self-acquisition can arise, firstly, from imitation; secondly, from necessity and custom (adaptation).

As the best example of imitation Koerner's [1] case may be cited, where a ruminating governess imparted her own affection to her two pupils; after the governess had been sent away, the two children quickly got rid of their rumination.

In many cases of rumination there is mentioned that the patients first, before the beginning of rumination, had for some time suffered from dyspeptic symptoms with regurgitations; thereafter they commenced to swallow what came up by regurgitation, and, finally, were aware of ruminating. In these cases the development of rumination from slight pathological conditions, by necessity and custom, can be plainly seen.

Most of the reported cases of rumination (in all the literature, to date, but one hundred and six cases of rumination have been described) are of the male sex, and belong chiefly to the professional and more educated classes (physicians, philologists, and lawyers); of the female sex only a few cases are reported as ruminants (in all nine cases, figured from the paper of Johannessen).

This alone would not prove that rumination, in fact, appears less frequently in men of the lower class and in the female sex; for very often a man of the working class does not deem his condition as a ruminant to be abnormal, and does not make mention of it to his physician. On the other hand, there are several people (especially among women) who would like to conceal their affection, and therefore do not speak about it. In consequence thereof, the correct relation of rumination, in reference to its distribution among the two sexes and the different social classes, cannot be ascertained from the cases reported in literature.

In the insane and idiots rumination has been found quite frequent. Thus G. Cantarono [2] found 9 cases of rumination among 400 male insane; among 300 female insane he did not find any ruminants. Bourneville and Séglas [3] likewise lay stress on the frequency of rumination in idiots, and also in epilectics.

5. **Duration of the Affection of Rumination.**—The duration of merycism is very variable; sometimes there is rumination keeping on uninterruptedly during the whole of life. Often rumination appears periodically in form of attacks; in these cases periods of rumination alternate with normal periods for intervals of different lengths.

Sometimes rumination suddenly ceases at the occurrence of an important change in the life of the merycist. Thus in literature a case is mentioned in which the ruminant stopped immediately after marriage.[4] But, there is also a report of another case in which rumination made its appearance a day after marriage.

These varying circumstances can only prove how deeply rumination is connected with the nervous functions.

6. **The Chemical Analysis of the Condition of the Stomach in Ruminants.**—The investigations made upon the chemical condition of the stomach in merycists are of the most recent time.

Johannessen [5] says briefly, in his elaborate paper on rumination, that at the end of rumination the ejected materials showed an acid reaction. Alt,[6] in 1888, was the first to make exact examinations of the stomach-contents in a ruminant. As soon as the patient suppressed

rumination it was found that the obtained stomach-contents, three to four hours after a trial-dinner, contained free hydrochloric acid, were rather hyperacid, and showed very retarded amylolytic qualities. But as soon as the patient had practised his rumination as usual, the obtained stomach-contents were less acid and the amylolysis was much better. Alt presumes that the rumination in his patient had the purpose of correcting the fault made by a deficient salivation of the food and the hyperacidity arising from it. "We would have," Alt says, "in rumination an institution for correcting the hyperacidity effected by a deficient salivation and the bad digestion of the amylaceous matters." Acting on this theory, Alt treated his patient with alkalies, with the result that the patient was less inclined to ruminate, and further, could suppress the same much easier.

In favor of Alt's theory would be perhaps the case of rumination reported by W. A. Hubbard.[1] A farmer, aged thirty-five, consulted Dr. Hubbard for, as he expressed it, "the restoration of his lost cud." This patient had the habit of ruminating his food since a period beyond his recollection, and had always enjoyed perfect health; now, for a month the rumination had stopped, and was immediately followed by dyspeptic symptoms. All medicaments proved to be of no use. Should we look with Alt upon rumination as a means of correction, it would be very easy to understand why the patient had the dyspeptic symptoms at the cessation of the rumination, and his wish and hope that "his habit will return as suddenly as it left him," justifiable.

Soon afterward, however, Boas[2] published a case of rumination where the chemical analysis of the stomach-contents showed the acidity to be diminished in a high degree. The treatment consisted in giving the patient hydrochloric acid, and the result was a diminution of the rumination and an amelioration of the glandular function of the stomach. In this way by Boas's case Alt's theory has been refuted.

Shortly afterward Juergensen[3] published two cases of rumination, with an absence of the free hydrochloric acid.

Nothing else has been written since, as far as I am aware, on the chemical analysis of the stomach-contents in ruminants.

After this brief preliminary discussion, permit me, Mr. President and Gentlemen, to introduce to you two cases of rumination which I have had under my observation.

Case I.—June 1, 1889. Ernst K——, aged forty-five, baker, had typhoid fever twelve years ago and was perfectly cured; otherwise the patient had always enjoyed good health. About seven years ago the patient suffered much from eructations and regurgitations after meals. For five or six years the patient noticed that, about one-half to one hour after meals, the food partaken of was rejected in small quantities from the stomach into his mouth; he would chew it again and swallow it, not having any bad sensation in doing so; the taste was even the same as during the meal. Meat would be ejected first, then bread, vegetables, etc. Cabbage and turnips were, likewise, ejected before the other food. When the patient drank water, this would never come up again; milk, however, would be ejected in a curdled condition after ten minutes, and was ruminated. The ruminating process once begun continued usually for one-quarter to one-half an hour.

The rumination in this patient made its appearance periodically, and was intercepted by free intervals of variable duration.

Since the year 1886 the patient had an attack of rumination lasting one year and a half. During the whole of this period the patient had to ruminate after each meal.

The duration of the other attacks was from three to six months.

Rumination has not been observed in any other member of the family of this patient. The patient believes that his affection arose from eating too quickly.

During the attacks of merycism the patient does not feel sick, but is annoyed by the rumination on account of the company present.

The rumination in this case is perfectly independent of the will of the patient, and the patient can neither ruminate spontaneously nor is he able to suppress the coming rumination. At present the patient has ruminated constantly for three months. For the past three or four years the patient has been subject to constipation.

The physical examination does not show anything abnormal. The patient is of medium height and well built; he, however, looks somewhat pale. The tongue is not coated. Seven seconds after the swallowing of water a rattling sound is heard on auscultation at the xyphoid process.

Examinations of the Stomach.—1. June 1, 1889. One hour after Ewald's trial-breakfast: HCl +, acidity = 54, erythrodextrin +, dextrin = 0.

2. June 6, 1889. When fasting: the stomach contains about 5 c.c. of a whitish turbid fluid; HCl +.

3. June 30, 1889. One hour after trial-breakfast: HCl +, acidity = 40, achroodextrin +, erythrodextrin + traces.

4. July 1, 1889. One hour after the trial-breakfast: HCl +, acidity = 50, erythrodextrin + much.

5. July 13, 1889. One hour after the trial-breakfast: HCl +, acidity = 100, dextrin +.

Case II.—March 26, 1890. G. P——, physician, aged twenty-seven, had gastritis febrica in his childhood, and in 1884 typhoid fever. Since his ninth year the patient has been troubled with his stomach; at that time, during a period of six months, the patient usually vomited after partaking of food, especially after fluid nourishment. Sometimes the patient had to vomit at the beginning of the meal, immediately after the soup, but could, nevertheless, continue to partake of his meal directly afterward. Since then the condition of the patient had become ameliorated, and instead of vomiting there appeared rumination.

The rumination in this patient appears spontaneously, about one hour after meals, and continues for about a quarter of an hour. The food comes up in small quantities (in form of boli). The taste is not sour; in chewing the cud the patient has a pleasant sensation.

When the patient partakes of fluid food only (as, for instance, beer, bouillon, coffee, milk), then it is not ruminated.

The patient has no ailments whatever.

In this patient the rumination appears periodically; thus, for instance, the patient ruminated three months, and then was free from it for about a year.

Even during the period of rumination the bowels act regularly; the patient, however, often suffers from belching.

He is able to ruminate at will any time there is food in his stomach. The act of rumination proceeds, even then, without any effort. In order to effect the rumination the patient closes his glottis and exerts slight pressure over the stomach by means of his abdominal muscles; the contents are then ejected in small portions into the mouth. Patient is able to do this in any posture; when sitting or standing, however, this act proceeds with more ease than in a recumbent position. In the same way the patient is voluntarily able to belch and to vomit; the latter in such a way that all the stomach-contents are ejected at once. In this way the patient is enabled to cleanse his stomach easily; he does this by drinking a large quantity of water and ejecting the same immediately after. The patient also has the faculty of stopping the vomiting at any moment he chooses, and in this way he can alternate vomiting with rumination. Patient has diplopia and is color-blind in one eye.

The father of the patient and several of his brothers

[1] W. A. Hubbard: Medical Record, July 31, 1880, p. 122.
[2] Boas: Berl. klin. Wochenschr., l. c.
[3] Juergensen: Ibid., 1888, N. 46.

and sisters are troubled with the stomach; the main symptom of their ailment is belching; nobody in the family, however, had rumination. The patient is able to suppress rumination, not feeling any pain in doing so. He does not know what causes the periodical attacks of rumination. After excitement the patient is more liable to fall into an attack of rumination.

The physical examination showed no abnormal conditions whatever. Patient is of medium hight, well developed, somewhat stout. Tongue perfectly clean. The stomach does not seem to be dilated. Seven seconds after swallowing water a rattling sound appears on auscultation at the xyphoid process.

Examinations of the Stomach.—1. During the rumination period. September 15, 1888. One hour after Ewald's trial-breakfast: HCL+, acidity = 50; erythrodextrin+, achroodextrin +. On the same day the patient took 1.0 salol in a gelatine capsule; the urine shows the salicyluric acid reaction (it becomes dark red on addition of a few drops of liq. ferri sesquichlor.) after one hour.

2. During an interval of freedom from rumination. March 25, 1890. One hour after trial-breakfast: HCL +, acidity = 54; erythrodextrin +, achroodex.+. After this examination the patient had to ruminate for three days, then the rumination ceased.

Epicrisis.—On considering the two afore-described cases of rumination, we must exclude heredity in both of them as being the etiological factor. In both cases the appearance of rumination was preceded by dyspeptic conditions, associated with belching and regurgitation or vomiting, in such a way that it might seem that the rumination was developed from this condition.

In both reported cases the merycism appeared periodically, the length of the period varying very much; thus in K—— one period of merycism lasted for one year and a half; another, however, only for three months. In the second patient a period usually lasts three months.

Patient P—— is able to voluntarily produce rumination at any time he likes, and can suppress it in the same way. This is quite different with patient K——; the latter is neither able to ruminate at will, nor can he suppress rumination.

In both patients, seven to eight seconds after the swallowing of water a rattling sound was heard at the xyphoid process in the normal way (Meltzer's Durchpressgeraeusch); the so-called "Durchspritzgeraeusch"—or the sound which appears right after swallowing water at the processus ensiformis—was absent. In this way the cardia—as far as can be ascertained by the swallowing sounds—proved to be normal as regards its contracting power.

It appears to be improbable that the relaxation of the cardia should be the only cause of rumination. For, on the one hand, the normal "Durchpressgeraeusch" was present in my two patients and in that of Boas. On the other hand, there are many people with the "Durchspritzgeraeusch"—which shows a relaxation of the cardia—who never ruminate.

Is the cardia in our merycists normally closed—as has just been shown—the same must open at the commencement of rumination, at the ejection. This opening occurs perhaps through the cardia-opening or relaxation-centre, and in this way rumination can begin. Luchsinger, from his experiments on animals, conjectured a centre for rumination in ruminant animals. It is not probable that such a centre exists *a priori* in men; in time, however, the cardia-opening centre may gain the faculty of presiding over rumination also. This centre for the opening of the cardia and rumination is, as such, independent of the will; in some people, however, there may arise a connection between the same and the will centres; then rumination can proceed voluntarily.

I have already remarked above that, in most cases, merycism does not appear as such at once, but that it probably gradually develops from eructations and regurgitations. When a patient suffers a long time from belching and eructations of some of the stomach-contents, he is sometimes liable to swallow the upheaved portion, and he is more liable to do that the oftener the regurgitations repeat themselves within a certain time.

Now, then, we know that the stomach is inclined to occasionally repeat some process which has been done exceptionally, or that a habit is easily liable to become developed. The following fact shows this most conspicuously: When taking up the sponge-experiments of Spallanzani on himself, Brown Séquard[1] was able to do it a short time, and once the sponge was ejected from the stomach; since that time Brown-Séquard, although not swallowing the sponge any more, had to eject everything he had partaken of.

We can imagine that the stomach would undertake regurgitations, perhaps first in consequence of dyspeptic conditions; afterward, however, especially when the ejected contents had been swallowed, as a kind of a habit to repeat this whole process. But as soon as food is ejected into the mouth early after a meal, at a time when it has not yet been changed much, the same will soon begin to do its usual work—the chewing—upon these returned materials from the stomach. In this way we could imagine the development of rumination in many cases.

In order to demonstrate what great influence habit might have, and to what skill one can arrive by it, I might mention the peculiar case of Le Juge de Segrais.[2] A boy of eleven years was able, after having partaken of a meal composed of different food-substances, to select one certain dish, which he liked most, for rumination; then only this favorite dish, without any admixture of the other food-substances, was ejected into the mouth. ["Il mangera de plusieurs plats, les uns aussi variés que les autres; celui qu'il aura eu l'idée de faire revenir, reviendra seul, sans mélange des autres."] As to the origin of the rumination in this boy the following is mentioned: The boy had lived several months in the country, where he had to partake of a great deal of milk prepared in various ways. The stomach, often being overfilled, regurgitations frequently appeared. The boy began to swallow the regurgitated food, and soon became used to this whole process—so much so, that he found great pleasure in doing it. Since that time the boy commenced to ruminate. The boy would ruminate those dishes especially which he liked most, in order to enjoy, as he himself expressed it, the taste of good things a second time. In time the faculty of selecting the favorite dishes, even after a meal composed of different foods, for rumination, was developed.

Darwin,[3] likewise, mentions the case of a man who was able to select the food he intended to ruminate.

Although self-acquisition and habit may sometimes be the originating cause of rumination, this affection, in order to explain the periodical attacks—its sudden stoppage and sudden appearance—must, nevertheless, be classed with the neuroses of the stomach.

After these theoretical explanations we might again return to our two cases of rumination.

In considering the figures of the chemical analysis of the stomach-contents of the two merycists, it might easily be seen that no relationship whatever can be found between the chemical condition of the stomach-contents and rumination. In one patient the condition of the stomach was perfectly normal in every respect, the chemical analysis showed the presence of hydrochloric acid in a normal quantity; the power of motion also proved to be adequate; Ewald's salol reaction appeared after one hour. In the other patient the chemical analysis of the stomach-contents varied greatly on different days. There was found once normal acidity (50), once rather subacidity (40), and once hyperacidity (100), whereas hydrochloric acid was always present.

From this last case the conjecture of Ewald is confirmed. This author,[4] in his book on the "Diseases of

[1] Cit: Bourneville et Séglas, l. c.
[2] Le Juge de Segrais: Journal de Médecine de Paris, 1887, p. 58.
[3] Darwin: Cit. Bourneville et Séglas, l. c.
[4] Ewald: Klinik der Verdauungskrankheiten, Bd. ii., 2d edition, p. 440.

the Stomach," says in reference to rumination: "I would not be astonished, the conditions being the same, if varying degrees of acidity were found in the same patient, because such changeable conditions are in the nature of many neuroses." The case of patient K—— furnishes the best example for such an occurrence, and from this we can infer that no connection exists between rumination and the chemical condition of the stomach.

Therapy.—Formerly hydrochloric acid, alkalies, narcotics, and the bitter remedies were tried empirically now and then, with apparent results for a short time, and sometimes without any influence whatever. Lately it has been tried to remedy the error—if any—ascertained after a chemical examination of the stomach-contents, and hydrochloric acid or alkalies have accordingly been given, with good results.

Koerner [1] tried giving small pieces of ice immediately after meals, and warmly recommends this method. Washing of the stomach has been practised by Johannessen,[2] and gavage (feeding through the stomach-tube) during fourteen days by Juergensen,[3] but with only temporary relief. All these remedies sometimes effect a temporary amelioration; a permanent cure, however, has never been achieved by therapeutic means. As an exception to this rule we might perhaps consider the moral treatment—*i.e.*, the patient determines not to ruminate and, as soon as a desire to ruminate appears, endeavors to suppress it. Poensgen [4] mentions two cases of merycism perfectly cured by this method.

Surely this moral treatment can only be applied in cases in which the rumination can be suppressed by the will-power of the patient, but not in cases in which the rumination is wholly independent of the will.

In treating Dr. G. P.. I have made use of this method; the recipe was: As soon as the patient feels any inclination to ruminate, to try with all his power to suppress it. The patient has carried out this rule quite conscientiously, and the merycism has since that time occurred only occasionally. In the treatment of the other patient (K——) different tonics and cracked ice have been tried, without any result.

Even though the therapy of rumination is very scant, we can console ourselves with the fact that the vital functions of the organism, as before mentioned, are never endangered by merycism itself, and it therefore must not be considered as a disease, but looked upon merely as a physiological anomaly.

122 East Fifty-ninth Street.

TRANSLUMINATION OF THE LARYNX AND OF THE ANTRUM OF HIGHMORE, WITH DEMONSTRATIONS.[5]

By W. FREUDENTHAL, M.D.,

NEW YORK.

As the subject of this paper is a relatively new one, I would beg leave to make a few explanatory remarks before demonstrating the apparatus.

This subject has engaged the attention of laryngologists for about a year, and it is to be deeply deplored that the reviver and real founder of it—Professor Voltolini, of Breslau—has died, alas! too early for us. Voltolini, to whom I am indebted for sending to me this apparatus, applied this method with almost youthful enthusiasm, and it is easily explained that at the beginning of these investigations he did not have the right idea of all he saw.

To find an English word for the German "Durchleuchtung" was not easily done. I finally decided to select the term Translumination, though Dr. J. Solis Cohen, of Philadelphia, suggested, in a private correspondence on this subject, that the word should be Transillumination. According to my opinion the former word corresponds more closely to the German term, and describes more accurately the process involved.

Now, to get a view of the interior of the larynx we apply this lamp to the external surface of the neck, either at the pomum Adami, or near the cricoid cartilage, and introduce the heated laryngoscopic mirror into the dark pharynx, and thus we obtain a splendid view of it. But this view is quite different from that ordinarily seen. The first thing that strikes the observer is the disappearance of different colors. The whole larynx shows a red dish tint of varying intensity. When we place the lamp at the level of the incisura thyreoidea, then the vocal bands and all parts above them appear of a beautiful red color (of course the epiglottis is dark). But when we place the lamp near the cricoid cartilage, then we get a better survey of the whole subglottic region down to the bifurcation of the trachea, and this view is often more satisfactory than that obtained by the common method. But it must be observed that we have to become accustomed to this peculiar view of the larynx, for it may be said we see mostly in the negative. What in ordinary illumination impressed us as a thickening or an enlargement of a solid mass, in translumination strikes us as a dark object. The rays of light cannot penetrate, and we infer, that a solid mass, or a mass subject to the same optical laws, must intervene. We will therefore be able to define more precisely the contour of a tumor, because we see how the mass differentiates itself sharply by its dark outlines from the other parts in view. Only a few days ago I saw a patient of Dr. L. Weiss, who had a tumor on the posterior wall of the larynx, extending between the two cartilages from the left arytenoid downward. We can see the circumference of it by means of translumination better than by the ordinary method. I will have the pleasure of showing to you the patient, and will be very glad to have the benefit of your opinion upon the case.

Furthermore, we will be enabled to differentiate, in a certain case, between a solid tumor and a cyst, and this point seems to me to be of sufficient importance to give the method a fair trial. A few weeks ago I operated on a man who, a few minutes afterward, happened to be seen by Dr. Hoch, of Philadelphia. The patient had a tumor, the greatest part of which was below the glottis. It was attached to the right vocal band at the front angle, and extended over a little to the left vocal band. By means of translumination I could easily determine that it was a solid tumor, not a cyst, and could gauge the exact size of it. It is true that you could have excluded a cyst in this case even without translumination, but there are cases where this is not so easily done, and for those I think translumination also of value.

In this man, by the way, we could see, the day after the operation, that the œdematous vocal band was much more translucent than before the œdema had set in, and this brings us to the other class of cases, where we have a greater penetration of light than normally. This, however, can only be seen where loss of substance has taken place, as in ulcerative processes or in other pathological conditions which admit a greater penetration of light. When Gottstein [1] says, "the reddened vocal band seems just as translucent as the normal," he is correct; but you cannot draw from that a conclusion as to the usefulness of this method generally. Certainly we cannot recognize these changes, but there are others which we can see so much the easier. So, for example, an œdematous vocal band is differently translucent than an infiltrated one. The first is of a strong, light red, *i.e.*, much redder than the normal, the last is much darker. That is a differentiation which is interesting enough to us.

We come now to the translumination of the antrum of Highmore. For the purpose of transluminating this and the nose, the patient takes the small lamp in his mouth; then we see through the nasal speculum that the nasal

[1] Deutsche Medicinische Wochenschrift, 1889, p. 840.

cavity is light; in fact, the whole face and the eyes seem light sometimes, as you yourselves will be able to see soon.

Now, when we take into consideration the way these rays of light have to pass, we will easily understand that the first condition of getting a view of the interior of the nose is the permeability of the nasal floor. Thus lately I had a case where, on the floor of the nose, not a very large broad-based polypus was found, which certainly did not occlude the maxillary foramen. Yet on this side translumination gave a negative result, while on the other a positive, *i.e.*, light. After removal of the polypus we succeeded in getting light on both sides.

Now if the nasal floor is permeable for the rays of light —which is the rule—then they spread to all sides, and we see the interior of the nose illuminated. If, however, it should remain dark, then we conclude that in the antrum there must be a body impermeable to the rays of light, more generally pus or a solid tumor. Should, however, a cyst filled with serous fluid be in the cavity, which, like in Voltolini's case, has enlarged the cavity and thinned its walls, then we would be able to see only so much the better. I would particularly like to draw attention to this point, as Voltolini seems to have been in error in this connection.

The presence of hypertrophied turbinated bodies does not seem to interfere, as one might imagine, with translumination, for I have often been able to see more distinctly, even when the hypertrophies were well marked. They seem to act like double convex lenses in collecting the light and making it more intense.

It might, perhaps, seem strange to some of you that the translumination of the nose depends so much on that of the antrum, as this lies so far externally to the nasal cavity. But this is certainly so. At present I am treating a gentleman for empyema of the antrum. Even after thoroughly removing all visible mucus from the nose, the affected side remains dark and becomes light only after I have syringed the antrum. So I can only assume that in pathological conditions of the antrum, perhaps the thickening of the mucous membranes, or of the bones or infiltration of pus on the floor of the nose, may also give the cause why the permeability of the light is completely excluded.

The non-appearance of light in the affected side is such an important symptom that by it we can make the diagnosis of empyema of the antrum. Heryng,[1] of Warsaw, reports ten such cases, where he with positiveness made the diagnosis by means of translumination. He operated on seven of them, so proving his diagnosis, and in the rest the diagnosis was beyond doubt. A few weeks ago Vohsen[2] reported excellent results of translumination, without giving any special number of cases. Since August, 1889, I have seen three cases of empyema of the antrum. In all three the non-appearance of light in the affected side could easily be noticed. I operated on them, and found that great masses of fetid pus in all three were discharged.

In those cases where we successfully apply Hartmann's air-douche or B. Fränkel's hanging-down of the head, where we have a permanent dropping of pus, or the different pains, tenderness on pressure over the canine fossa, etc.—in those cases we can make the diagnosis without translumination; but there is besides these a large number of them where, even to the most experienced diagnostician, great doubt exists. For those cases, I am sure, the translumination will remain of permanent value. For I cannot believe that to-day anybody would prefer to make an exploratory extraction of a tooth, or an exploratory incision, which is always more or less combined with pain, when he has at his service such a painless and easily accomplished method.

But important as it may be in a given case to make the diagnosis of an empyema, as valuable is it at times when we can say with certainty, "In this patient there is no pus in the antrum!" Once I came very near having a tooth drawn in a patient, when I was convinced by translumination that I was in error. The patient had no pus in the antrum.

Now permit me to add a few words on the pharynx. Voltolini introduced the small lamp behind the uvula, and could see not only the soft palate transluminated, but looking through a nasal speculum saw the whole nasal cavity. This, however, can only be done in rare cases, as the lamp becomes heated very quickly and burns. The application of cocaine, suggested by Voltolini, I would not recommend, as, the sensibility being reduced, the parts are apt to be cauterized unintentionally. So much for the pharynx.

The lamps of Voltolini have been modified by various authors. In Heryng's modification[1] where to Türck's spatula an electric lamp is fastened, I do not see an improvement. Vohsen's lamp, however, which prevents the rapid overheating of the small lamp, seems to be more conformable to the purpose. But I have not seen it yet, and can give no particulars about it.

The lamp for the larynx I have modified myself.[2] I was able to see with it in some cases more distinctly, and can handle it easier.

And now, gentlemen, if you want to try this method, allow me to give you some points:

1. For the exploration of the antrum an absolutely dark room is necessary, for that of the larynx not.

2. Never work without a rheostat, if you don't want to break too many lamps; and,

3. Never forget to ask your patient to take his toothplate out of his mouth before examining his antrum. For you might be tempted to diagnose empyema of the antrum on both sides, if you do not use that precaution!

In conclusion, let me say that if I have convinced you of the necessity of this new method of exploration, and if you give it a fair trial, then the purpose of this paper is accomplished. I believe, I have proved to you that, contrary to the opinion of Roth[3] and Gottstein,[4] this method is a valuable one also for the larynx. That it plays a great part in the diagnosis of diseases of the antrum, is, I think, already beyond doubt; that it, however, will enlighten us about the still very obscure diseases of the other accessory sinuses of the nose, this, I hope and wish sincerely.

Early Laparotomy for Catarrhal and Ulcerative Appendicitis.—Professor Senn concludes as follows: 1. All cases of catarrhal and ulcerative appendicitis should be treated by laparotomy and excision of the appendix, as soon as the lesion can be recognized. 2. Excision of the appendix, in cases of simple uncomplicated appendicitis, is one of the easiest and safest of all intra-abdominal operations. 3. Excision of the appendix in cases of appendicitis, before perforation has occurred, is both a curative and prophylactic measure. 4. The most constant and reliable symptoms indicating the existence of appendicitis, are recurring pains and circumscribed tenderness in the region of the appendix. 5. All operations on the appendix should be done through a straight incision parallel to and directly over the cæcum. 6. The stump after excision of the appendix should be carefully disinfected, iodoformized, and covered with peritoneum by suturing the serous surface of the cæcum on each side over it with a number of Lembert stitches. 7. The abdominal incision should be closed by two rows of sutures, the first embracing the peritoneum, and the second the remaining structures of the margins of the wound. 8. Drainage in such cases is unnecessary, and should be dispensed with.—*The Journal of the American Medical Association.*

Clinical Department.

PREGNANCY AND SUCCESSFUL DELIVERY IN A CASE OF ALMOST COMPLETE CONGENITAL ATRESIA VAGINALIS.

J. J. E. MAHER, M.D.,

NEW YORK.

SEPTEMBER 18th, Mrs. F——, aged thirty, said she expected some trouble in her confinement; she had an operation over a year before for a false pregnancy, otherwise had never complained but once when her menses began. She thought she was in the ninth month, but proved to be in the eighth.

Vaginal examination revealed carunculæ myrtiformes as the remains of the hymen, a short vagina, and an absence of the cervix uteri. Here arose a question of diagnosis which I will pass over. There was a depression in the false bottom, situated near the posterior wall. The speculum confirmed what the finger had discovered. A Simpson's sound could not be passed through the barrier at any point—not even through the depressed spot. The finger in the rectum passed the end of the sound pressed against the apparent bottom of the vagina, and reached a more resisting body beyond. This I took for the missing cervix. The thickness of the obstructing medium I could not as yet determine. At this point, there was a possibility of making a grave mistake which some observers are said to have made before, namely, of concluding there was no opening, because Simpson's sound could not effect a passage.

Dr. C. C. Lee corroborated my diagnosis, and after much search succeeded in passing a probe 1.5 mm. in diameter. He recommended the gradual dilatation of the opening found by laminaria tents.

The obstructing medium, at the site of the opening, measured (gauging the constriction of the first tent used), 6 mm. in thickness, and was composed of all the structures proper to the vaginal wall. At the end of a week the finger could penetrate to the cervix.

November 1st, 8 A.M., I saw the patient in labor, which had begun about midnight. Membranes had ruptured early. Os dilated during a pain about twelve millimeters, and was thick and rigid. Vertex presentation in L. A. A. position. Pelvis ample, bladder and rectum empty. Vagina washed out with one-half per cent. solution of creolin, was lubricated with a creolin ointment. The vaginal stricture was dilated by Barnes' bags until 5 P.M., when the vagina began to become very sensitive.

Eight A.M., next day the os measured 5 mm. Sensitiveness not complained of. Bag No. 3 was dilated completely and left *in situ*. It was expelled at the end of an hour. After a further delay, it was evident she would never expel her child, and interference became imperative. In the afternoon the thermometer in the vagina indicated a temperature of 103° F. The pulse was 150.

After 4 P.M., Dr. George E. Abbott put her under chloroform. I passed a long Simpson's forceps, seized the head at the brim, brought it gradually down upon the perineum through the stricture to the vulva. A laceration of perineum being imminent, the forceps was removed. The *vis à tergo* soon drove the head through the vulva. The woman vomited, and the rest of the child was expelled *in toto*. The S. O. B. circumference of the child's head was 33.8 ctm. Dr. Abbott took the child in charge, but it could not be resuscitated. The highest temperature during the puerperium was 102⅘° F. on the evening of the second day. The vaginal discharges had become so virulent at this time as to convert every little scratch on my hands into a painful pustule.

Having implicit confidence in creolin, and being convinced that all the infection arose from absorption at the outlet; I ordered the napkins to be saturated with the creolin solution, and dried before being applied to the vulva. Of course creolin injections were also used. The only other drug used was tr. aconit. gtt. ij. every hour for the fever and pulse.

The third day the highest temperature was 99⅘° F., with a pulse 86. All smell of putrescence disappeared after the use of creolin napkins, and was never found again.

The patient did very well and was up on the tenth day. Seventeen days after delivery she reported herself well at my office four miles away. This is, I believe, the first case on record treated by the laminaria tents and Barnes' bags.

SUPRA-PUBIC LITHOTOMY.

BY WILLIAM NEILL, M.D.,

CHARLESTOWN, W. VA.

I REPORT the following case on account of the unusual size of the stone, and because of the excellent result following the operation of supra-pubic lithotomy in the hands of the general practitioner.

Thomas D—— had had irritable bladder for the last ten years. On October 19, 1889, I was called to relieve him, suffering from almost complete retention of urine. In attempting to introduce a soft rubber catheter I encountered an obstruction at the entrance of the bladder. A silver catheter was substituted, which passed to the same point, and refused to go further. In my endeavors to urge it onward, I was enlightened as to the character of the obstruction by a distinct metallic click. Every effort compatible with safety was made to drive back what I believed to be an impacted or encysted stone, and it was only after several attempts that I finally gained entrance. The urine passed, but in much less quantity than was anticipated, owing, as it proved afterward, to the reduced capacity of the bladder by reason of organic contraction.

I explained the condition to the patient and his family, and suggested an immediate operation, which was consented to. On October 21st, I operated by the supra-pubic method. The parts were shaved, and made as aseptic as possible. After the patient was anæsthetised the bladder was first washed out, and then filled to its utmost capacity with a warm solution of boracic acid (grs. x. to ℥ j.). Not possessing or having time to procure a rectal colpeurynter, I dispensed with it.

The incision was made in the linea alba, three inches and a half from above down to the pubic bone, dividing the abdominal walls to the transversalis fascia, which being more carefully divided, exposed the bladder to view. I removed its contents, and divided its anterior wall sufficiently to introduce the index-finger. Realizing that I had a stone of more than usual size to grapple with, I was compelled to enlarge the opening. Accordingly, doing so, I encountered the peritoneum, which was held up while making the cut. In removing the stone I experienced considerable difficulty, as my forceps were too small to embrace it, and finally was compelled to lift it from its bed with my two first fingers. It was afterward found to measure two inches and nine-tenths in length, two inches and five-tenths in width, and one inch and nine-tenths in thickness, and weighed six ounces, less thirty grains. Its chemical nature was not ascertained, but it resembled the uric-acid variety.

After the stone was removed the divided edges of the bladder were carefully stitched with catgut sutures to the abdominal walls, and the wound closed, leaving an opening for drainage; a rubber drainage-tube was inserted, but removed in a few hours on account of the pain and annoyance which it caused. The wound was frequently sponged with a solution of bichloride (1 to 1,000), and dusted with iodoform, and covered with a layer of borated cotton. No catheter was left in the bladder, the urine passing through the opening for fourteen days, before passing through the natural channel. After which the wound rapidly healed. The patient made a good recovery, and is at present in perfect health.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, May 17, 1890.

MEDICAL OFFICERS OF PASSENGER STEAMSHIPS.

WHAT we have had to say, recently, in regard to the very unsatisfactory nature of the medical service on the transatlantic steamers, is corroborated by the report of the Health Officer of the port of New York, Dr. William M. Smith, to the Quarantine Commissioners. We referred to the dangers to which the passengers were exposed on account of the neglect of the first principles of sanitation on the ships, and of the incompetency of many of the ship surgeons. Dr. Smith takes another view of it, being naturally most concerned with the obstacles put in the way of an efficient quarantine through the carelessness and ignorance of the medical officers of passenger steamships.

If a Quarantine officer had only to detect and remove developed cases of contagious diseases among passengers on their arrival, his troubles would be comparatively insignificant. It is the possible existence of latent contagion among the well, which has been communicated to them through exposure to developed cases of disease—the medical officer having failed to detect its character sufficiently early and then to isolate the sick—that causes him anxiety. An instance of this sort is given in this report. The Deputy Health Officer reported a case of suspicious eruptive disease on the person of a passenger, that the ship's surgeon insisted was a case of acne. The officer refused to give the ship *pratique* without consultation, and it required but a brief examination to determine that the case was one of small-pox, in the third day of development, modified somewhat by vaccination in early life. Dr. Smith does not mince matters when he comes to comment on this and similar cases, for "neglect," he says, "on the part of the medical officer to detect the contagious diseases that develop among passengers during the stage of invasion, and to properly isolate them when discovered, is but another name for incompetency, and is even less pardonable than the ignorance which prevents their prompt recognition and their proper management."

But there is something to be said for the surgeon. He has little or no authority, even in matters purely medical, and the more he tries to do his duty the more likely he is to incur the enmity of the captain and the disapproval of the company that gives him his bread and butter. As Dr. Leet has so clearly shown in his pamphlet, to which we have referred in a previous article, the hospitals on shipboard are not infrequently put to other purposes, and when the surgeon demands them for the accommodation of his patients there is no end of grumbling, and the poor doctor is sometimes made to feel most painfully the displeasure of the other officers, which he has incurred by doing what was his duty and nothing more. Indeed a case in point is related in Dr. Smith's report. A certain steamer arrived with one of the crew sick with small-pox. The surgeon of the steamer had isolated the case, and while the man was still in the hospital another man was put in the same room, in the belief that he was suffering from the initial symptoms of the disease. The diagnosis in this case was found to be erroneous, and the man was ready to return to duty the morning before the arrival of the vessel at Quarantine; but the doctor thought best to keep him in the hospital so that the health officer could do as he thought fit in regard to the disinfection of the clothing and the disposition of the man himself. The captain heard of this, and calling the surgeon, asked with an oath why the man was kept in hospital if not sick, and ordered him back to work at once. When, on arrival of the ship at Quarantine, the surgeon was asked why the man was allowed to return with infected clothing to his place among the rest of the crew, he gave his testimony with reluctance, saying that he was sure it would cost him his place for telling.

It is easy enough, of course, to find a remedy for this state of things, but it is less easy to get the remedy applied. Only competent men should be employed, and they should be paid salaries proportionate to the value of their services, and should have the necessary authority to enforce the carrying out of sanitary measures. The only certain way of securing this reform is to take away, in a measure at least, the government of the surgeon from the steamship companies, and to make him a public officer responsible to the government under whose flag the vessel sails. There is no more crying evil, the Health Officer says, in the transatlantic passenger steamship service at the present time than the inefficient medical service on many of the regular passenger steamers to this port. He proposes the following measure of relief, which, if it were followed out, could not but result in a vast improvement in the quality of the ship doctors:

"First. A medical marine service under the control and management of the government (or a board of control responsible to it) whose flag the steamer flies, will be the first and most important step toward reform.

"Second. The adoption by such authority of the following rules is essential:

"1. Medical officers with good professional qualifications and high character.

"2. Adequate compensation for the medical officer. The minimum compensation for properly qualified medical officers should be not less than $100 per month.

"3. The service should provide for promotion to the charge of better-class steamers of the line, with increase of rank and compensation proportionate to length of service and general efficiency.

"4. The surgeon's tenure of office should depend on his ability and efficiency, and his discharge from service should be effected only by charges made and sustained before the government board which certified to his qualifications for appointment.

"5. Marine medical officers in charge of passenger ships should have their duties distinctly defined, their responsibilities clearly determined, and their status as officers well understood through rules and regulations made by a supervisory board.

"6. The authority of the medical officer should be independent and absolute in those medical and sanitary matters which affect the lives and health of those on board the ship, or which may, by neglect or improper management, expose the health of the people in this country."

We have quoted at some length from this report because we feel that the matter is one of paramount importance, affecting as it does so closely the prosperity of the community. No one is in better position to observe the shortcomings of ship surgeons than a Quarantine officer, and the testimony he bears to their general inefficiency, and to the obstacles thrown in the way of those who really are competent and who try to do their duty, should have a wider publicity than it is likely to obtain in the pages of a legislative report.

THE ABOLITION OF CAPITAL PUNISHMENT.

There has perambulated down the ages a legend to the effect that "the doctor takes life easily," and it might be inferred that he would regard the taking of life by society without any sentimental protest at least. We believe it is true that the physician looks at the question of capital punishment very objectively, and passes judgment upon it mainly as he would upon a question of therapeutics—for this is what it is. If society can better preserve and protect itself against criminals by their strangulation or electrothanatosis, why, then, these measures should be employed. No question of first principles or inherent rights or sentiment is involved. The public mind is being exercised upon this matter just now, and we hope with fruitful results. It appears as if the death penalty were a necessity in the early stages of social organization, but that as civilization advances it becomes useless and unwise.

"ONLY A DOCTOR."

Dr. David W. Cheever recently gave an address to the graduating class of the Harvard Medical School which was replete with practical wisdom and elevated feeling. All the advice given has, no doubt, been given before; but it does good to repeat and emphasize the points which young physicians—and their elders too—should keep ever before them as guides to successful living.

"The first requisite is *work*. Cultivate good manners. Be reticent. Always show a cheerful face. Never give up a case while the patient breathes. Stay at home; be ready in your office. Medicine is not a trade, it is the noblest profession; cling to that thought. The Golden Rule is the true code of ethics. Be gentlemen, and not rude, grasping boors; respect others' rights and you will be respected."

Such are some of the sentiments which Dr. Cheever has laid down, and they are sentiments which will be warmly echoed by every one.

But Dr. Cheever has made some mistakes in his advice, and mistakes which no one occupying his position as a teacher and moulder of young minds ought to commit.

He says: "Do not allow yourself to be known as anything but a doctor;" "unlike the law, medicine leads to nothing else save science."

We submit that it is just because doctors have always inculcated such sentiments as these that doctors hold so small repute in public life. Socially the doctor is often shunned because he can or will talk nothing but his everlasting "shop"; politically the highest office he can legitimately seek is that of an assistant coroner. The wishes of a great State Medical Society have less weight than that of a single ward "boss."

This all comes not alone from the exacting nature of his duties, but much more from the fact that the doctor has been constantly inoculated with the deadly virus of the Cheever sentiment, "Do not allow yourself to be known as anything but a doctor."

Would it be any harm if the doctor were known also as a philanthropist, or a sanitarian, or a statesman, or an anthropologist? Successful physicians have filled all these rôles, but it has been far too rarely.

We quite agree that professional work is first, and beyond everything else, in the doctor's life; but the times are changing; the physician belongs to the best educated classes, his mind receives through his professional work the best kind of training. He owes something to society in general as well as to the sick. Every doctor ought to have some interest outside of his profession. It will make him a more useful and interesting man and a more skilful physician. The constant and assiduous pursuit of the calling of physic tends to produce a routine in methods of thought and action. The doctor, like the overtrained athlete, gets "stale." Let him, therefore, always cultivate an antidote, and let people gradually discover that though he is a good physician he is something else also.

PROCREATION OF THE CRIMINAL AND DEGENERATE CLASSES.

Our brethren of California are fully up to the times in matters of a social and sanitary kind. The President of the State Society, Dr. Walter Lindley, in his annual address, asks:

"Why should not every man and woman who desires a license for marriage be required, before such license is issued, to show the County Clerk a certificate from the County Physician, certifying that both he and she were free from any taint of consumption, gonorrhœa, syphilis, or scrofula. I ask you, gentlemen, to give this subject, which to me seems a very important one, your serious consideration."

He further adds: "Knowing, as all surgeons do today, that castration and spaying are simple operations that can be performed with about as little danger as the ancient rite of circumcision, I do not hesitate to advise that the following classes be required by law to submit to this procedure: Idiots, those who commit or attempt to commit rape, wife-beaters, murderers, and some classes of the insane."

We admire the doctor's generous breadth of view in proposing to castrate the men as well as to spay the women. Fortunately, however, it is a physiological law that the degenerate classes have little procreative power and tend to die out of themselves. What society needs most, therefore, is the adoption of such ethical and social measures as will prevent the development of new vicious and criminal families.

News of the Week.

Tenth International Medical Congress.—By direction of Count Arco, the German Ambassador in Washington, the Consul-General of the German Empire in New York, Mr. A. Feigel, sends the following:

Conditions and Rules Referring to the International Medical and Scientific Exhibition in Berlin, August, 1890.—I. The Exhibition will be opened at 11 A.M., on August 2, 1890, and closed, probably, August 11th, P.M., in the Landesausstellungs Park; the sections of the International Medical Congress will meet in the same place. Provision will be made for dark chambers, rooms for experimental purposes, and appropriate demonstrations by experts. The Exhibition is limited to the following objects: New or improved scientific instruments and apparatuses for biological and strictly medical purposes, inclusive of those for photography and spectral analysis applicable to medicine. New pharmacological, chemical, and pharmaceutical materials and preparations. New foods. New or improved instruments for operations in medicine, surgery, special branches, electrotherapy, etc. New plans and models of hospitals, convalescent homes, and establishments for disinfection and bathing, arrangements for nursing and transport. New hygienic apparatuses. New tables and charts of a statistical nature. Preparations and models. Teaching apparatuses. Medical literature.

Applications are expected before May 15, 1890,[1] and will be received by the Secretary General of the Congress, Dr. Lassar, Berlin, N. W., Karlstrasse 19. They must be marked "Ausstellungsangelegenheit," and accompanied with a printed visiting or business card containing name and address. II. Of each application there ought to be two copies. It is requested that it should contain a brief and accurate description fit to be used in the compilation of the catalogue. III. The decision as to the admission of all or part of the proposed exhibits rests with the special or general boards of organization; they will send an immediate reply. IV. The cost of every square metre, or part of a square metre, of floor or table surface is 10 marks, of wall surface 6 marks. Two metres in height of the wall are free for those adjoining the wall. Exhibits in the interior of the hall pay for one-half of the walk immediately surrounding, in addition to the space occupied. V. Tables will be furnished. Cases, shelves, repositories, must be procured by the exhibitors under the supervision of the committee. Electric light, steam power, etc., can be had by special arrangement. VI. Inflammable objects are excluded. Insurance of those admitted will be secured free of cost, if notice of their value have been given. VII. Packing and unpacking is free of expense to foreigners. Great care will be taken but no responsibility. Expressage by Messrs. Jacob and Valentin, Berlin, O. Holzmarktstrasse 65. VIII. The exhibits must be delivered on or before July 20th. Foreign goods will be free of duty, but certificate—to accompany the goods—ought to be obtained from the exhibition office, Karlstrasse 19.

Form of Application.—The undersigned being acquainted with the conditions and rules referring to the International Medical and Scientific Exhibition in Berlin, August, 1890, requests admission for the following exhibits: Space wanted.—Floor surface, length, breadth; wall surface, breadth, height. Exhibition will take place (a) in own case: adjoining the wall? inside? (if the latter add a diagram); (b) on tables to be furnished by the committee: in flat cases? exposed without them? on shelves? the wall surface above the table is required to the height of? (c) on the floor, without case, etc.; (d) as drawings, diagrams, or in narrow cases attached to adjoining walls? value for insurance purposes; special requests; brief notes for catalogue; name, etc.

[1] Count Arco has made such arrangements that applications coming from the United States will be received until July 1st.

A Medical "Trust."—According to *The North American Practitioner*, a member of the Chicago Board of Health, a west-side physician, the Mayor, and a noted criminal lawyer have combined to form a "Medical Trust," so called; which seems, however, to be only a kind of Provident Medical Association. Members are required to pay one dollar per month, quarterly, in advance, in lieu of all professional services which they require. This includes medicines, and presumably bottles to contain the same, but whether or not nurses are also provided by the association remains yet to be discovered. *The Practitioner* seems to think the scheme a novel one, when in fact it is a very old one, and has worked with some success in England.

The College of Medicine of Southern California held its Annual Commencement on April 16th, and graduated a class of seven.

The Attendance at the forthcoming International Congress at Berlin, this summer, is estimated to exceed five thousand, and special arrangements will be made in consequence.

Injustice to a Physician.—A physician of this city was called to treat a patient who had been a morphine-taker. She was suffering great pain and desired hypodermic injections of the drug. The physician substituted distilled water. At the end of five months, the patient having become convalescent, the physician confessed the substitution, doubtless believing the facts would be a relief to the family. About the same time, also, he rendered his account for professional services. On seeking to collect the latter, payment was refused, and suit was thereupon entered, the defendant making response that the "charges were extortionate, and deception had been practised." As may be imagined, the defence was a quibble to avoid payment. The legal complications, however, were such that the suit was compromised and the physician accepted one-third of the original bill.

Dr. Benjamin Duval, aged sixty, died in Frankfort, Ky., on May 10th, of consumption.

The St. Louis College of Physicians and Surgeons.—Dr. Louis Bauer has resigned as dean of this college, and Dr. A. S. Barnes has been elected in his place. The war between the Ins and the Outs in this institution is now carried on in the daily papers. An Out makes a statement in the *Republic* which the leading In characterizes as untrue, and so harmony creeps on apace.

Dr. Robert W. Taylor has been appointed Lecturer on Venereal Diseases at the College of Physicians and Surgeons.

Large Fees.—In this age of rapid railway travel the medical consultant finds its possible to visit clients in the remotest parts of the continent. In fact a medical man nowadays thinks nothing of travelling a thousand miles away from his home, on a few hours' notice, to see a patient. Recently Dr. Park, of Chicago, at the request of a patient, went to San Francisco, and received the princely fee of $25,000 for his services, which extended over a period of several weeks; and we learn that Dr. Samuel Sexton went last week to St. Paul, Minn., where he successfully performed an operation on the ear, for the cure of deafness, and for which a similarly large fee was given.

The South Carolina State Medical Association, at its annual meeting, held in Laurens, elected the following officers for the coming year: *President*—Dr. Thomas P. Bailey, of Georgetown; *First Vice-President*—Dr. E. Miller, Florence; *Second Vice-President*—Dr. P. A. Wilhite, Anderson; *Third Vice-President*—Dr. Thomas McCoy, Laurens; *Recording Secretary*—Dr. W. P. Porcher, Charleston; *Corresponding Secretary*—Dr. O. S. Missildine, Charleston; *Treasurer*—Dr. H. W. DeSaussure, Charleston. The next annual meeting will be held at Anderson. The following papers were read before the Association: "A Probable Case of Cyst of the Spleen," by Dr. J. K. Gulder; "The Cause of Tubercular Disease in the Negro," by Dr. T. J. McKie; "Laparotomy for Fibroids in the Uterus, Dermoid Cysts of the Ovaries, and Ectopic Gestation," by Dr. Cornelius Kollock; "Young Eyes," by Dr. C. W. Kollock; "Intraligamentous Cysts, Colecystotomy of Pregnant Women," by Dr. R. B. Rhett, Jr; "Report of Cataract Cancer," by Dr. C. W. Kollock; "Origin of Sputa in Subacute Cough," by Dr. W. P. Porcher; "Six Recent Cases of Laparotomy for the Uterine Appendages," by Dr. R. A. Kinloch; "Physical Culture," by Dr. E. T. Darby; "Retention of Menses," by Dr. O. B. Mayer, Jr.; "A Surgical Case," by Dr. B. W. Taylor; "Advance in Obstetrics," by Dr. P. Gourdin DeSaussure; "Vesico-Vaginal Fistula," by Dr. F. W. P. Butler; "Report of the Committee on Ophthalmology," by Dr. George Howe; "Report of the Committee on Practice of Medicine," by Dr. T. P. Bailey; "Arterio-Venous Aneurism," by Dr. Manning Simons; "The Treatment of Pelvic Peritonitis," by Dr. Thomas Legare; "Report of the Committeee on Surgery," by Dr. O. B. Mayer, Jr.

Dr. F. N. Otis has been appointed Professor Emeritus of Genito-Urinary and Venereal Diseases at the College of Physicians and Surgeons, New York.

The Rhode Island Medical Practice Bill has been defeated in the legislature by a vote of twenty-two to eight. The physicians of the State were apparently not very active in support of the bill.

The Royal College of Surgeons.—Sir Morell Mackenzie has recently made a lively and vigorous attack upon the Royal College of Surgeons, in the *Fortnightly Review*. Americans are but little interested in the controversy, but we fancy that on a plain statement of the merits of the case their sympathies would go with Sir Morell Mackenzie and the members of the College who are fighting for the principle of representation. The members support the College largely by their fees, but they have no vote or voice in the management, and not even a right to use the College building.

Dr. Arthur H. Wilson, of Boston, died suddenly a few days ago of heart trouble. He was a graduate of the Harvard Medical School, and served during the latter part of the war of the rebellion as assistant surgeon of the Seventh United States Veteran Volunteers.

Burial of Dr. Cronin.—The remains of Dr. Cronin, which had been lying in a vault in Calvary Cemetery, Chicago, were interred a few days ago. A fund has been started for the erection of a monument to his memory.

The Johns Hopkins Medical College.—The new movement regarding this proposed institution has already been noticed by us. The circulars and collection blanks which have been sent out set the final day for collection March 1, 1891, and they contain this proviso, "on condition that women be admitted to the school, whenever it shall open, on the same terms as men, it being understood that the amount [subscription] be returned to me [the subscriber] by June 1, 1891, unless at least $100,000 be raised, and unless the admission of women to the school be assured by vote of the trustees of the university." Following this announcement comes the declaration from one of the Board of Trustees that preparations for the establishment of the school are being made, and that some of the professors have been engaged. As to the admission of women, he says that the trustees have not voted on that point. It seems that the sum of $100,000 has already been given for the school, and that a number of enterprising women are trying to raise another $100,000, with which they hope to buy their way into the school. A considerable part of the sum has already been raised. Medical co-education has been tried in a number of places in this country; it seems to be the opinion, however, that the best results are obtained either by independent schools or by the "annex" system.

Prize Essay Medical Society of the County of New York.—Essays in competition must be sent to one of the undersigned on or before October 1st. Other things being equal, preference will be given to essays which exhibit original work on the part of the author. The subject is simply restricted to the field of what are called the departments of medical study. The value of the prize is $100. L. Bolton Bangs, M.D., *Chairman*: Egbert H. Grandin, M.D.; Andrew F. Currier, M.D.

Death of Mrs. J. Marion Sims.—Eliza Theresa Sims, wife of the late J. Marion Sims, M.D., died in New York City, May 11, 1890, at the age of seventy-four. The announcement of her death can find no more appropriate place than in the journals of a profession in which her husband won a world-wide fame, leaving to humanity, in the triumphs of his skill as a surgeon, the means of relief from ills hitherto incurable. To commemorate his matchless genius there is soon to be unveiled in this city a statue in bronze, a fitting tribute of admiration from fellow-workers in the healing art, and of love from woman, to benefit whom his labor was directed. To those who know the story of his life and its brilliant achievements, which carried the fame of American surgery throughout the civilized world, there can be no tribute to his memory which is not fully shared by the brave, ambitious, tender, and loving wife, who watched over, worked for, and helped to win immortality for Marion Sims.—W.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 1, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Academy Coupons. — DR. F. A. CASTLE offered a resolution, to be acted upon after a month, authorizing the academy to issue a series of bonds, not to exceed thirty thousand dollars, to bear five per cent. interest, payable on or before 1900. The sum thus raised was to go toward completing and embellishing the new building.

Adjourned Discussion on the Relation of Peripheral Irritation to Disease.—The discussion was opened by Dr. F. H. Bosworth, with a paper on "The True Relation of Diseased Conditions in the Upper Air-passages to the so-called Nasal Reflexes" (see p. 551).

Reflex Chorea.—DR. A. JACOBI discussed this phase of the subject. He said there was a large number of conditions in which chorea was present, but not always in the relation perhaps of a reflex. It was seen in various cerebral states as apoplexy, tumors in different parts, inflammation of the meninges, of the cerebral arteries, of the spinal cord, in sclerosis and softening of the brain or cord, in bilateral, sometimes unilateral paralysis, in epilepsy, etc. Chorea was also due to blood diseases—to rheumatism, anæmia, general exhaustion, and was sometimes found during the process of growth. It might be due to direct nerve influence, as fright, or neuritis, but other cases were of reflex nature in the restricted sense, and of this kind he would speak more particularly of nasal reflexes. Among other disorders of which it was a reflex, he named those pertaining to the digestive system, the sexual organs, one case on record was due to fissure of the anus, a number to cicatricial contraction, etc.

Nasal Reflex Chorea.—During the past ten years much attention had been given to diseases which were considered of reflex nasal origin. Among writers who had made mention of reflex nasal chorea were Seiler, McKenzie, Hack. The speaker had published a paper on the subject in 1886. He might say that for dozens of years he had seen many cases of the following description: a child, three, seven, or ten years of age, would show a number of symptoms which to most people did not appear those of any morbid condition, but simply the result of bad habits, for which it was punished. The parents were told that with puberty or sooner the child would get well, but instead it often grew worse. The symptoms consisted in local convulsive movements, as twitchings about the face, winking of the eye or eyes, horizontal and vertical frowning, twitchings of the angles of the mouth, shrugging of the shoulders, jerking of the arms, sometimes throwing about of the arm, hawking, slight cough, some nasal catarrh. This lasted a number of years, being better perhaps during the warmer months. On examination the nose would be found the seat of catarrh, the mucous membrane thickened, considerable discharge present, glands of the neck swollen, particularly near the angle of the jaw, sometimes there was ozæna, one or both nostrils more or less obstructed, sometimes deviation of the septum, in every case a good deal of pharyngeal catarrh, the tonsils hypertrophied and presenting a number of follicular cavities, in a number of cases a little œdema. Since publishing his paper in 1886 he had seen at least four cases of general chorea due to local conditions of this nature, and altogether he had seen at least a dozen cases in which all the members participated in the choreic movements, which had no other cause than chronic naso-pharyngeal catarrh, deviation of the septum, ozæna, hypertrophy of the tonsils, etc. This form of chorea differed from usual chorea in that the convulsive movements were not made worse by voluntary attempts to use the muscles.

Treatment.—These cases were likely to last a long time because not receiving proper treatment. The movements began in the face, therein differing from ordinary chorea, and were likely to be accompanied by mental dulness rather than by mental irritability as in the usual form. Local treatment was called for, but he had found milder measures than those often adopted of recent years suffice. Salt wash, with a small proportion of alum, would sometimes be sufficient; in some cases the galvano-cautery was called for. A cure could not be effected until the enlargement of the tonsil had been overcome. While he did not wish to exaggerate the importance of local reflexes in the causation of this or other diseases, yet attention should be called to them if we would effect a cure in certain cases.

Peripheral Irritation in its Relations to Diseases of the Womb and its Appendages.—DR. CHARLES CARROLL LEE said that in discussing this phase of the subject he would dismiss at once the more serious conditions, such as phthisis, which were said to sometimes follow disease of the uterus or its appendages, and call attention to well-marked neuroses or hystero-neuroses which best illustrated the subject. Omitting chorea, of which many cases were dependent on uterine and ovarian disease, he mentioned among peripheral irritations the following: 1. Disturbance of the surface temperature. 2. Neuralgia, such as spinal irritation, sciatica, migraine. 3. Special forms of headache, such as pressure upon the vertex while the rest of the head was unaffected. 4. Neuroses of the gastro-intestinal tract, including the familiar symptom of persistent vomiting of early pregnancy. 5. Neurotic conditions of the breasts, sometimes of a most aggravated character. 6. Irritation of the respiratory tract, producing not only occasional dyspnœa, but unmistakable attacks of asthma. 7. Hysterical affections of the joints and of organs of special sense, particularly the eye.

It was undoubtedly true that these illustrations of peripheral irritations, like all neuroses, were symptomatic of some more deeply seated disease elsewhere, and only by combining proper treatment there with improvement of the general health could we expect success. It was a striking clinical fact that mal-conditions of the uterus exercised far more influence in this direction than did diseases of the ovaries and tubes, however pronounced the latter might be. Treat the ovarian condition as thoroughly as was possible, yet the neurotic complication would almost surely persist until the accompanying disease of the womb had disappeared. For neurotic conditions ablation of the uterine appendages was not only useless, but often left the patient worse than she was before. Yet it was true that in pyosalpinx and extensive ovarian degeneration these organs should be removed.

The Relation of Peripheral Irritation to Disease Considered Therapeutically.—DR. SIMON BARUCH read the paper. The chief aim in therapeutic endeavor must be at the source of irritation. The case which removed his scepticism with regard to nasal reflexes in disease occurred in a boy aged sixteen, who had definitely marked epileptic attacks. He discovered an enchondroma occluding the nostril, and on removing it the epileptic attacks disappeared, the boy having only one attack subsequently. This was four years ago, and bromides were ceased seven months ago. He regarded four years' immunity from attacks as proof of cure. In migraine, asthma, neuralgia, and some other conditions, one should not overlook a possible source of the trouble in the nose. Here cocaine was of diagnostic value. Operations on the nose were not so simple as some specialists had taught, for in this city two serious results had followed a skilfully executed surgical procedure on the nasal structures, in one death finally taking place after severe hemorrhage.

Nine years ago he was subject to attacks of migraine which caused him a great deal of suffering. He went to Dr. Derby, who ordered glasses for double myopic astigmatism, which not only gave perfect vision (which other glasses had failed to do), but also caused complete disappearance of migraine. He approved, however, of Dr.

Roosa's censure of those who were practising mutilations of the eye for all conceivable troubles.

Unless subjective symptoms or lesions pointed directly to the sexual organs, the physician should be careful not to turn his patient's thoughts in this direction. He believed that removal of the tubes and ovaries except for well defined pathological changes was never called for. Cases of epilepsy and other reflexes had had their origin in scars, in gastro-intestinal disturbance, etc., and had been cured by treatment of such local conditions.

It appeared, then, that peripheral irritations as the cause of disease had been well established; that they should be looked for when other causes were not apparent; that harmless measures should be tried before resorting to mutilations.

Peripheral Irritation from Dental Causes.—Dr. Meyer L. Rhein read a paper on this phase of the subject, which he thought had received too little attention except in dental societies. One case with attacks strongly resembling those of epilepsy due to dental disease was cited in which the patient allowed nine years to pass before getting up sufficient courage to submit to treatment. There were numerous cases of visceral disturbance, neuralgias, even tetanus, etc., due to dental irritation. In fact this form of peripheral irritation ranked second to no other in the production of disease, especially those relating to the nervous system—neuralgias, chorea, insanity. He thought inflammations in the nose travelling downward not infrequently caused inflammation of the peridental mucous membrane. Two of the most common causes of dental irritation, and two which were easily recognizable, were exposed pulps in the teeth and alveolar abscess. It had been commonly advised to at once have the teeth extracted in such cases, whereas it was only in exceptional ones that the skilful dentist could not restore the parts to a healthful condition. The value of the teeth in the preservation of a normal state of the alimentary tract had been too much underrated in medical works.

Old Teachings Under a New Guise.—Dr. R. W. Amidon quoted some recent writers, particularly in France, who had cured headache, migraine, and various conditions by applications of cocaine, cautery, and other measures to the nose or other parts, and asked whether we had here anything really new. Further quotations from writers of forty years ago showed that the same remedies had been employed at that date and before under the name errhines, etc. For instance, Dr. George B. Wood had written of errhines: "By their stimulation of the [Schneiderian] membrane they sometimes prove useful in defective secretion of the nasal mucus, or unhealthy dryness of the membrane in chronic inflammation of the same, and in paralysis of the sense of smell, and of the soft palate. By depletion they tend to relieve inflammatory conditions of the neighboring parts, as of the antra, the frontal sinuses, the eustachian tube, the ears, eyes, face, and scalp; their revulsive influence is useful in the same inflammatory affections, and also in neuralgia of different parts of the face and scalp. Obstinate chronic ophthalmia, excessive sensibility of the retina, amaurosis, rheumatic conditions of the eye, frontal and facial neuralgia, earache, chronic otitis and deafness, obstinate headaches, and even chronic inflammation of the brain or its meninges are complaints which offer indications for the use of these medicines. In reference to their excitant impression on the cerebral centres, they are used to obviate faintness or syncope, or restore suspended respiration, to compose irregularities of respiration of a purely nervous character. Suspending and moderating epileptic paroxysms, etc." Among such remedies were mentioned aromatic powders, tobacco, veratrum album, turpeth mineral, etc. Dr. Amidon thought here was an important therapeutic field which had been too much neglected. He testified also to the importance of restoring the general health.

Dr. O. B. Douglas expressed his appreciation of the value of the two meetings devoted to the discussion of peripheral irritation in relation to disease, and Dr. A. Jacobi said that while he had committed himself to the view that chorea was sometimes thus caused, yet we should be extremely cautious in attributing central disease to such an origin. It was easy to make a mistake in diagnosis. For instance, for a number of years the profession was erroneously led by the statements of an illustrious man or two to look for sexual irritation as a cause of central disease, particularly phymosis as a cause of infantile paralysis. Yet Dr. Jacobi had sought twenty years for proof of this view, and had never found a case, and he knew now that he never would find one.

Transferred Irritations.—Dr. M. A. Starr called attention to facts having an important bearing on this subject contained in a paper written by Dr. Dana some years ago, on so-called reflex pains, or transferred pains. He showed that painful or disturbing irritations in a given organ might be carried by the sympathetic system to the spinal cord, there produce an irritation which was carried to the brain, and the brain, being accustomed to receive from that part of the cord, irritations or sensations from other parts of the body, might wrongly refer the disease or pain to this part. In this way gastro intestinal irritation might excite pain in the shoulder, and pain in a stump be referred to the amputated hand, etc.

Where are those Higher Centres?—Dr. Quimby, in referring to the higher centres spoken of in Dr. Starr's paper read at the previous meeting, wanted to know what and where they were.

Dr. Starr said it was easier to ask a question than to answer it, but he might reply that schemes of development of the nervous system, especially that put forth by Hughlings Jackson, implied a series of centres, one above another, and the highest in the series which had yet been accepted were the motor centres in the cortex. Hughlings Jackson stated that there still higher ones, and located them in the frontal lobes.

Dr. Quimby said he did not question the existence of such centres, but he doubted whether it was weakening of the higher centres and their loss of control over the lower ones which caused explosions of the latter, as suggested by Dr. Starr. The explosion might be due rather to too great a strain placed upon the lower centres, as when a man's temper gave way while the higher restraining centres might not yet have been exhausted.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Ninety-second Annual Session, held at the Hall of the Faculty, Baltimore, Md., April 22, 23, 24, and 25, 1890.

Dr. Aaron Fredenwald, President, in the Chair.

First Day, Tuesday, April 22d.

Address of the President.—The session was called to order at 12.30 P.M. After the reading of the minutes of the last meeting by the Secretary, the President delivered his address.

The Modern Hospital.—This subject had been suggested by contemplating the significance of the two new hospitals which had been completed in this city in the past year. The Johns Hopkins Hospital was opened on May 7, 1889, and the new City Hospital on December 23, 1889—the former the consummation of a most munificent foundation, the latter called into being by a religious order. The modern hospital should offer bountifully all that is made possible by an advanced science and by a refined humanity.

The origin of the hospital is remote and far from simple. It did not emanate from any single civilization. Many nations and ages contributed to its present development. The origin of the hospital has been traced as far back as the temple of Æsculapius at Titanus.

1134 B.C. The oldest Buddhist accounts of hospitals reach to the middle of the third century B.C. The Spaniards found on their arrival in Mexico that the Aztec civilization had amply provided for the sick and disabled in hospitals. These data show that hospitals had long been considered a public necessity. Besides the hospitals called Hôtels Dieu, established in France, the rage of leprosy, which continued up to the fifteenth century, was a potent factor in promoting the growth of hospitals. In England the first hospital was established by Lanfranc, Archbishop of Canterbury, in 1070, and in Germany Berlin was the first city to open hospitals, about the same date. The famous hospital at Milan, with a capacity of over two thousand patients, was opened in 1456, and is still used. Military hospitals were first built in the sixteenth century, when Ambrose Paré established a hospital during the siege of Metz. The English did not have military hospitals until later, because it cost more to cure a soldier than to levy a new recruit. In North America Quebec is said to have had the first hospital, in 1639. In 1658 a hospital was organized on Manhattan Island. To Benjamin Franklin and Dr. Thomas Bond is credited the original of the present Pennsylvania Hospital. In reviewing the history of hospitals, it is seen that they are of no recent origin, but while formerly they were intended for the poor, the needy, the debilitated, and those without means, now, as is well known, there are many conditions in which a patient can be better provided for in a hospital than in his own home. Before closing the story of the hospital and its advantages, combined with the skill of the physician, it should not be forgotten to be mentioned the efficient, intelligent, and faithful nurse, to whose untiring devotion good results are so often due.

SECOND DAY, WEDNESDAY, APRIL 23D.

Abortion and its Effects, the subject of the Annual Oration, was delivered by Professor Joseph Taber Johnson, Ph.D., M.D., of the University of Georgetown.

All agree upon the importance and wickedness and frequency of abortion. It is steadily on the increase. Questions of drainage, sewage, quarantine, vaccination, and antiseptics are all important, but it is undoubtedly true that by the unnecessary and intentional destruction of the human fœtus more lives are lost than are saved by all these agencies combined. Abortion occurs once to every five labors, and ninety per cent. of all married women have at least one miscarriage during their child-bearing life. Violent and premature expulsion of the products of conception occurs so frequently that State legislation has been attracted to it, and in Massachusetts it is said that the native American stock in that State is dying out, the increase in the population being principally among the foreign population. One hundred years ago it was rare to see families of less than six children, and frequently there were ten; now it is rare to find as many as three, and often only one or none at all. Cultured Boston, the proud city of the Puritans, has become a Roman Catholic Irish city, rejoicing in a mayor with the classic name of O'Brien. Notwithstanding the endeavor by the American Medical Association and some writers in the distribution of "advice to mothers," the practice of abortion is not only not decreasing but is increasing each year. The difficulty of conviction for producing abortion is shown in the statement of the Attorney-General of Massachusetts, that of thirty-two arrests and trials of abortionists in that State, in a period of eight years, not a single conviction resulted, and this fact is equally true in Germany, a country otherwise very strict in the execution of its laws. The small risks that abortionists run in being convicted, and their large gains, all increase the frequency of abortion. Physicians are partly to blame for this state of affairs. They should endeavor to get proper legislation to punish abortionists, and even the women themselves who permit it—women, indeed, who would shrink from any other crime. The luxuries of life and the expense of maintaining a large family should not be considered as excuses. The fœtus is as much alive before quickening as afterward, and the crime is equal at any time after conception. As to the effects on the woman, it is well known that miscarriage is more dangerous to the woman than labor at full term. It is not too much to say that two-thirds of the work of the gynecologist finds its chief cause in this evil. Much good can be done by the honest physician in preventing these dangers too frequent.

SECTION ON SURGERY.

CHAS. G. W. MCGILL, M.D., CHAIRMAN.

Hydatid Cyst of the Liver (Suppuration); Operation and Recovery.—DR. C. F. BEVAN read a paper on the above subject, and presented the man cured. It was an unusual case in this country; although on looking up the literature he had found more cases than he had expected. The diagnosis was not difficult after the abscess was opened.

DR. J. W. CHAMBERS then related a series of cases of head injury.

Operation for Hæmorrhoids.—This was the subject of a paper by DR. S. T. EARLE. In the discussion which followed, DR. WM. H. WELCH, in referring to Dr. Bevan's paper, said he had seen about half a dozen cases of hydatid cyst of the liver in this country. The books give the impression that the disease is of every-day occurrence. It does occur. He had found it in a number of pigs, and in three instances he traced the disease and found that two of the pigs got it in this region. It comes from dogs. He had examined the intestines of a large number of dogs, but had not found the tænia echinococcus. This is not wonderful, for it is very minute. Most of those found are when the dog has been fed for it. The two points in diagnosis are that it is possible to make a diagnosis by the microscopical examination of the fluid withdrawn, containing the membranes and characteristic hooklets. Also, it is possible to arrive at a very probable diagnosis by a chemical examination of the fluids, which usually contain no albumen.

SECTION ON PRACTICE OF MEDICINE.

GEORGE J. PRESTON, M.D., CHAIRMAN.

The Nature and Treatment of Hysterical Paralysis.—THE CHAIRMAN spoke on the above subject. Hysterical paralysis is one of the most prominent and characteristic members of that group of symptoms to which has been applied the general term hysteria. The profession has been slow to accord this disease its proper place. The patient's relatives express indignation at the term. From a philological point of view the term is incorrect. Hysteria is the purest type of the functional disease, although in the eyes of the laity it is organic. We do not understand hysteria because we do not understand the intimate relations and working of the brain, and have to fall back on theory in our attempts to explain results. However, experimental physiology and pathological records in the light of this work have given us so many indisputable facts and suggestions that we may say we have a good working theory. Hysterical paralysis is of cortical origin, but the cortical motor cells are not affected. The trouble is obscure. The cause of hysteria may be bad training in childhood, over-indulgence, undue excitement, sudden fright, and such like conditions; also any lowering of the general nutrition. The pathogenesis of hysterical paralysis, according to the theory proposed, might be expressed thus: Certain abnormal stimuli, or usual stimuli acting to an extraordinary degree, produce in the higher centres a condition of exhaustion such that these higher centres are no longer able to stimulate the lower or motor centres to a degree sufficient to produce a discharge. Paraplegia is the most common form of hysterical paralysis, but hemiplegia is not uncommon, particularly following marked hystero-epilepsy. It may be of all grades;

the differential diagnosis is not easy, and this has led to sad mistakes in prognosis. The treatment requires tact and patience.

SECTION ON OBSTETRICS AND GYNECOLOGY.

B. B. Browne, M.D., Chairman.

The Removal of Submucous and Intra-uterine Fibroid Tumors by Enucleation and Traction, with Report of Ten Cases, was the subject of a paper read by The Chairman. After relating the methods heretofore in use, and describing at length the ten cases, he drew the following conclusions: 1. By traction and enucleation we get the benefit of normal uterine expulsive power. 2. We do not incur the risk of amputating a portion of the uterus, or of cutting off a portion of the tumor and leaving it in the cavity. 3. We leave a clean intra-uterine surface. 4. We have a perfect means of diagnosis between a projecting fibroid tumor and inversion of the uterus.

Fibroid Tumors Complicating Pregnancy.—Dr. R. M. Hall read a paper on this subject. There are different kinds of fibroid tumors. Out of 74 in the non-pregnant woman 4 were in the cervix. Myomata form no obstacle to pregnancy. The connection between sterility and the presence of fibromata is very striking. Fibroids are more common in married women. Of 1,634 women with fibroids, 1,192 were married and 442 single, or about three to one. Fibroids are common in the colored race. Almost all uterine tumors in the colored woman, not carcinomata, are fibroids. Fibroids are frequent among sterile women. Of 1,554 married women with fibroids, 476 were sterile, or 1 to 3.05.

A Double Monster, belonging to the class of terata katadidyma of the kind dicranus and diprosopus. Dr. L. E. Neale exhibited this specimen, which had been presented by Dr. George A. Fleming. It was from a multipara. Dr. Fleming had made digital examination, and, feeling between the two heads, had very naturally diagnosed a breech presentation. The child was born, and the two heads appeared, revealing the true condition. It is of interest to note that both heads cried at once after birth. It lived a few minutes, then gasped and died. Dr. Neale also exhibited a case of acardia and acephalus occurring in his own practice.

In the discussion which followed Dr. B. B. Browne, in referring to a case of failure in Cæsarean section, referred to by Dr. Hall, said that the idea was to perform the section, but as the pulsation in the cord had ceased such a thing was out of the question. Still, it was well to keep such cases in view, and be ready for the operation to be done at any time.

Dr. R. M. Hall referred to a case of a single woman, a primipara, who gave birth at the seventh to eighth month to a monster with the cleavage from below. When he reached the house it was born. The specimen was examined by Dr. Councelman, who found two cords and two membranes.

Dr. L. E. Neale had a case which he was not able to exhibit. A colored woman gave birth to her first child, whose upper extremities were much like the flippers of an amphibious animal. She said she had been in the habit of going to the park and watching the sea-lions; but on further questioning her she said she did not go to see the sea-lions until in her fifth month, and if there is anything in the theory of maternal impressions, which Dr. Neale was inclined to doubt, the impression should be made in the first eight weeks to affect the fœtus. He had not much faith in maternal impressions.

Third Day, Thursday, April 24th.

SECTION ON MATERIA MEDICA AND CHEMISTRY.

C. H. Jones, M.D., Chairman.

Therapeutical Progress in 1889.—Dr. E. F. Cordell read a most excellent *résumé* of this subject. No great additions have been made to our therapeutical resources, but a careful weeding and selecting has been going on. Interest still centres in the antipyretics, analgesics, and hypnotics. To the former class exalgine is the most important addition. Pyrodine is another antipyretic which will probaby have a short life. Thalline is now rarely used. Sulphonal no longer attracts the attention it once did. Chloralamide does not satisfy the wants of the therapeutist. Liebreich denounces somnal. Amylene hydrate and urethan are mild hypnotics. In antiseptics we have a valuable addition in creoline. Hypnotism is a very powerful agent for good or evil. The treatment of ataxy by suspension has yielded results worthy of notice. The advantages of electricity as a therapeutic agent are often exaggerated. The Hyderabad Commission has brought in results remarkable, and that will hardly be accepted. Among the minor points to be noticed are the treatment of constipation by glycerine suppositories. The dangers of prescribing the alkaloid strychnia are such that it should always be ordered as a salt, which is much more soluble and safer.

In the discussion which followed, Dr. P. C. Williams spoke of the difficulties of finding a reliable hypnotic, especially in cases of hysteria. Sulphonal is slow and uncertain, and fails in hysterical cases, although it is good in mere wakefulness. He endorsed what was said about chloroform. Do not put a patient under it too gradually. The best inhaler is a cylinder. He gives chloroform chiefly in labor, and then uses it whether the heart is affected or not. Its use prevents unnecessary strain on a diseased heart.

Dr. J. D. Blake thought the danger of chloroform was at the beginning. The nervous system should become gradually accustomed to the chloroform.

Dr. C. H. Jones thought the Hyderabad Commission had shown nothing new in its investigations.

Dr. J. J. Chisolm has fought the battle for chloroform for twenty years. The Hyderabad Commission had sustained every point he had made.

Dr. A. K. Bond thought the pupil should be watched in chloroform anæsthesia. This was more important than the pulse or respiration.

Dr. Hiram Woods said there was no use in watching these signs. Some have a susceptible heart and will die anyhow.

Dr. I. E. Atkinson thought the skill of the anæsthetizer should be taken into account.

Dr. J. W. Chamber thought the amount and method of giving it made very little difference. Some die anyhow.

Dr. L. McLane Tiffany said neither chloroform nor ether was the best. The medical man should confine himself to neither, and use his judgment and discretion.

Dr. George H. Rohé thought the cases should be selected.

Dr. C. G. Hill gave chloroform at first and followed it up with ether.

This paper was further discussed by Drs. W. R. Monroe, J. H. Branham, J. E. Michael, and R. Winslow.

SECTION ON ANATOMY, PHYSIOLOGY, AND PATHOLOGY.

Herbert Harlan, M.D., Chairman.

A Résumé of the Literature on So-called Trophic Nerves was given by Dr. John C. Hemmeter. The smallest part of the material for this study came from physiological experiments, and the largest part from clinical observation. From these studies we conclude that the function and nutrition are but different phases of the same thing—the general metabolism of the body—hence all nerves are in some sense metabolic nerves. The nutritive processes are under constant regulative influence by the nervous system, but a proof for the existence of so-called trophic nerves, pure and simple, has not been furnished, except to a certain extent, in these specific nutritive processes occurring in muscles and glands. Most so-

called trophic disturbances can be explained by loss of vaso motor innervation.

FOURTH DAY, FRIDAY, APRIL 25TH.

SECTION ON PSYCHOLOGY AND MEDICAL JURISPRUDENCE.

JOHN S. CONRAD, M.D., CHAIRMAN.

Dr. Charles G. Hill read a paper on "Psychological Progress as Measured by the Advances in Cerebral Localization."

SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOSCOPY.

H. C. MCSHERRY, M.D., CHAIRMAN.

The Exclusion of Light is not Beneficial in the After-treatment of Cataract Patients.—DR. JULIAN J. CHISOLM, in a paper on this subject, gave his experience during the past four years in the treatment of cataract operations. His method of after-treatment, as is well known, is revolutionary to all experience in this direction. Instead of dark rooms, absolute quiet on their backs in bed, and all the bodily restraints which ophthalmic surgeons deem so necessary for the successfnl healing of the corneal wound, including the closing of both eyes under heavy compresses and bandages, Dr. Chisolm practises just the opposite. He does not put his patients after cataract operation into dark rooms; he does not treat them in bed; he does not bind up their eyes; he does not use any bodily restraints. He only closes up the eye he has operated upon by a strip of soft salicylated silk isinglass plaster, and then leaves the other eye open, so that the patient can see to walk about, to feed himself, and to make his own toilet at bedtime and when he gets up in the morning. The eye operated on can be daily inspected through the diaphanous adhesive plaster. By the fifth day the corneal wound has healed and the strip of adhesive plaster removed. He claims for this treatment better results than he ever got in previous years when he practised all the restraints in general use. His experience, which covers hundreds of cases, shows that eyes treated in lighted rooms escape much of the irritability which is found when the bandages are removed in the dark-room treatment. Since the operation without iridectomy has been reintroduced, Dr. Chisolm's extractions are by the newer method. In his hospital one hundred and fifty of these have been done with the most excellent results. Hernia of the iris very seldom occurs, and not more frequently than in the practice of the most skilful eye surgeons who still think the bed treatment and absolute quiet are essential items in the success of the operation. Dr. Chisolm has had thirty years' experience as an eye surgeon, and has performed upward of eighteen hundred cataract extractions, a much larger experience than any other surgeon in the United States. For twenty-five years he treated the patients in dark rooms under thick compresses. For the past four years he has practised just the opposite treatment, of closing only the eye operated upon, and using light rooms with no bed confinement, and without bodily restraints of any kind. His experience has proven to him that the new plan of after-treatment is by far the better one. Hence he makes war against what he deems the relics of a former bad surgery which should be abandoned, and should be if only for the needless annoyances which it inflicted upon over-docile patients.

Volunteer papers were then read by Dr. George H. Rohé, on "The Statistics of One Hundred Obstetrical Cases;" by Dr. A. K. Bond, on "The Lung Diseases of the Prevailing Influenza;" and by Dr. W. R. Monroe, on "The Use of Nitrogen in Therapeutics."

Officers Elected.—The following officers were elected for 1890-91: *President*—Dr. T. A. Ashby; *Vice-Presidents*—Drs. G. H. Rohé and J. McP. Scott, of Hagerstown, Md.; *Recording Secretary*—Dr. G. Lane Taneyhill; *Assistant Secretary*—Dr. Robert T. Wilson; *Reporting Secretary*—Dr. William C. Canfield; *Treasurer*—Dr. W. F. A. Kemp.

One hundred new members were elected.

Correspondence.

THE VALUE OF VITAL STATISTICS.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: When by derangement of the conditions of life dissolution is induced in the individual body, the physician last in charge of the case is required to insert the "cause of death" in the printed form sent out by the State Bureau of Vital Statistics. For this service to the State no compensation to the attestant is announced, but the physician rendering it may at least mentally assume that in so far as he promotes the cause of science by such service, by so far will his reward be found in the general conclusions for the benefit of the whole people.

The value or usefulness of these reports to the State bureau and to the people at large, rests entirely upon their correctness and truthfulness. They are the premises which, true or false, correct or incorrect, determine the conclusion, making it a scientific truth or a deceptive fallacy. If they are false, all deductions therefrom are false; if they are incorrect, all conclusions from them are incorrect. The entire superstructure of the State bureau rests upon these individual reports, and, however elaborate and ornate it may be in whole or in part, stability and value is given to it only by the truth and correctness of the attesting physician.

It is a cause of no small disappointment, however, to find, at a glance into the death records of any part of the country, that the incompetency of many so-called physicians is there so flagrantly conspicuous as to destroy totally and at once all confidence in the utility of the measure as of any possible benefit to the public in general or to the profession in particular. In no way, perhaps, is the abhorrent ignorance of the incompetent physician more graphically demonstrated than in these death reports. There he exhibits not only his ignorance of the A B C of professional knowledge, of anatomy, physiology, and obstetrics, but also of scientific terms, of the diagnostic significance of symptoms, of discriminatory knowledge, etc., but there also is displayed his school-boy chirography, his original orthography, his innocence of the simplest rules of grammar, of the use or misuse of capital letters, of punctuation, etc. Let me demonstrate by submitting here a few of the "causes of death" taken from such death records, copied *verbatim et literatim*. "Paralysis," "Dropsey," "Old age," "Cancer of the Liver," "Consumption of the lungs," "Congestion of Liver with Heart Disease," "He got Choked with a Piece of Meat while Eating Dinner," "Old Age and General Braking Down of the system," "Apeoplexey Found Daed in Bed." "Irregular priesentation at birth," "From swallowing a brass button," "Cattarhal Inflamation of Throat and Glands of the head," "Inflamation of Lungs and Bowills," "Old Age, and injuries caused from a fall," "Paralysis and old age," and, by the way, the physician who reported this, in five out of nine deaths reported by him in three months has given "old age and paralysis" as the cause of death! "Ossification of the Cerebral Artereis," "Ossification of the Artereis of the base of the Brain," "Passiv Congestion of the brain caused by dillitation of the heart." These three were given as the cause of death by a physician who shows as great predilection for arterial degeneration at the base of the brain, even when no autopsy is held, as the other does for paralysis and old age.

What reliance can be given to deductions drawn from data like this? Is it possible to construct a scientific principle from material so incompetent? Is not the time of the State bureau worse than wasted, and its labor worse than idleness when engaged with such pseudodoxy?

In view of this whole matter, the recent abrogation of our one-year-old State law requiring preliminary education to the study of medicine looks like an inexcusable and overt act to block or turn backward the wheels of progress. The legislators who are responsible for that uncalled-for repeal may some day die of paresis, or of fatty degeneration of the brain, but, as they look over the shoulder of the attesting physician they must not complain if they see him inscribe as the cause of death, Ossification of the Heart, or Paralysis of His stummick.

J. D. KELLY, A.M., M.D.

LOWVILLE, N. Y.

CROSSING THE BORDER LINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The free dispensary abuse is not the only one that needs correcting. Is it not enough that our ranks are full of physicians ever ready to gain popularity in unprofessional ways? Owing to this fact we and they lose sixty per cent. of our bills. The public view the practice of medicine as "missionary work" in which a physician is by lawful compulsion compelled to engage and make visits when called upon, and that he must wait a year for his money. I say this is the popular view, but there is one law they are pretty well posted upon, the exemption clause of debtors, and they are ever ready to creep out of paying their bills by changing physicians upon some trifling pretext.

Free dispensaries, established more to push into popularity a few men than to relieve suffering, are insignificant compared with what I am about to speak. Newspapers, both daily and weekly, secular and religious, and those published in the interests of arts, and groceries, have their medical columns for the purpose of enlightening the public upon the best methods of treating disease.

Nor is this all, we have paraded before us in the telegraphic press reports of our daily morning papers, for the benefit of the public and the "poorly educated" physicians in country practice, the treatment of an impending epidemic by some "eminent professor," as the public explain it, "at the head of the faculty in Z.," and one who confessedly has never seen a case of the disease. A press report of that kind is responsible for more lay prescribing than all the quacks in Christendom could accomplish, for the quacks are familiar with the use of aconite, quinine, antipyrine, bromides, and chloral; but no living man can measure the length, breadth, height, or depth of the drug-store sales of articles supposed to be good in an influenza, and sold to all who would purchase. If the dosage of these medicines was not familiar with the laity who bought, the gentlemanly proprietor or his clerks would kindly furnish the required directions.

Within the last few years a new system of abuse has been heaped upon the medical profession in the form of medical legislation. The very object at which it is aimed, the protection of the regular physician, has failed. Legislation on the practice of medicine has gone wild. A regular physician living near the border of States having these laws is in a quandary; an honored and respected citizen at home, if he crosses the border line to visit patients he becomes a criminal, an associate with drunkards, thieves, and other vagabonds, at the police court bar. All of this reads nice for those not "engaged in trades, but in scientific work." One writer whom I cannot recall says, "we should educate the public to believe that these practice laws are for their benefit, and not that of the profession." That is stuff, the laws were intended to protect the medical profession and the public alike, and they do not protect the public at all when the nearest physician is over the line in another State, and you cannot get him, owing to vile legislation. Legislative interference is not alone aimed at practice upon the human economy. In some States it is a criminal act for a person to practise veterinary medicine and surgery on his own horse unless a D.V.S.; to practise dentistry, unless a D.D.S.; to practise pharmacy unless he is an examined and passed pharmacist; and the latest "fad" is "the bill introduced into the Ohio legislature forbidding a physician from administering any medicine whatever to his patients except in case of emergency." After this bill is passed, I hope one will be introduced, forbidding physicians to practise at all. The object of this article is not to oppose decent legislative enactments against "empiricism," but as each State has a different law, the matter is in a pretty difficult snarl, and wants straightening out immediately by proper national legislation, for physicians have, as other citizens of the United States, interstate as well as State rights.

The physician of to-day needs not only the protecting influence of State law, but also interstate law. A regular physician has the right by virtue of his education and examination to practise medicine in the State in which he is examined, passed, and qualified. The State appoints the laws by which he becomes an M.D. Can that right be wrested from him by later laws. I reply, no. That right is a life-long constitutional right, and is so recognized by the United States Constitution. I doubt very much if the abridgment of that liberty can be constitutionally made in another State. If it can, one of the solutions of this problem must be an appeal to Congress, that the physician whose diploma is verified by a seal of the State Board of Health, or of the State Board of Examiners of the State in which he resides shall give him the liberty to practise in any State in the union without the necessity of passing a new examination. This allows the surgeon and the specialist the latitude they desire.

It's a very poor rule that works but one way, for specialists shall not practise in my vicinity, if I know it, while hailing from a different State, no matter what their standing, unless I have the same opportunity in theirs, except they qualify, by humbling themselves before a State Examining Board, and are duly licensed. JUSTICE.

OUTRAGEOUS QUESTIONS IN TAKING THE CENSUS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: "For a man's house is his castle" (*et domus sua cuique tutissimum refugium*), said the learned Coke, two or three hundred years ago. If the accounts, however, published in the New York *Sun* of May 7th and 10th, of the manner in which the census is to be taken be correct, our castles will afford very scanty protection to our *lares* and *penates*, and against the disclosure of much that is fraught with pain and sorrow in many homes. I refer especially to these questions, which must be truthfully answered under penalty of arrest and fine:

"Whether suffering from acute or chronic disease, with name of disease and length of time afflicted.

"Whether defective in mind, sight, hearing, or speech; or whether crippled, maimed, or deformed, with name of defect."

Now, we all know that in this State no court can compel a physician to disclose knowledge obtained by him in his professional capacity concerning the ailments of his patients. More than that, he is distinctly forbidden by the law to disclose such facts. And yet an army of men is empowered to exact information from every household in the land, in regard to maladies of such a distressing character as to shroud that household in an atmosphere of gloom. The fruit of inherited vice, cancer, scrofula, ovarian tumors, consumption, ataxia, Bright's disease, everything dire and dreadful, must be told to the enumerator, who is paid two cents for the account he gives of each person. Of the uselessness of such statistics, particularly as regards the first set of questions, I will say nothing.

Questions like these, if the answers be enforced, are a blow against the sanctity of our homes. And yet it is stated that the local superintendent of the census was making arrangements with the police department to ar-

rest any person who refused to answer the questions (including, of course, those I have quoted) of the census-taker. It seems to me a mistake that the first set of questions should find a place in the list. I do not believe any court of law would uphold enforcing an answer to them. It is certain, at least, that many wretched invalids will be made more so by being confronted in their distress by such an inquisition If these questions be correctly given, they are a stigma upon civilization and humanity. I cannot believe, however, that invalids can be obliged to state to any one, except whom they may elect, the nature of their maladies. Respectfully yours,

H. B. MILLARD, M.D.

NEW YORK, May 12, 1890.

SCIENCE AND COWARDICE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I suppose that it is among the laws of nature that there should always be some old fossils hanging to the wheels of progress that by their *vis inertia* stay the movements of scientists and prevent them, having once got started, from going "on and on forever."

I am among the old men now, and during the thirty years in which I have been actively engaged in the practice of medicine have seen the rise and fall of a whole army of hobbies. Some of these have been amusing, some productive of much evil, but from one and all of them the slow-going, painstaking "General Practitioner," whose name seldom appears in the MEDICAL RECORD and is not known outside his own narrow circle of friends, has been able to learn something; and by collating facts and rejecting fancies has done more to rear up our present medical science than he ever gets credit for.

As the astrologer gave us astronomy, and the alchemist chemistry, so the quack doctor, the homœopath, and the scientist with his one idea, have had their wheat sifted from the chaff by this old General Practitioner, who has chosen the good and refused the evil, until the question may very pertinently be asked, "Are we the old or the new school?" Twenty-five years ago, "ulceration of the cervix" was fashionable. Every woman with any self-respect had it, and I saw one which had been scientifically cauterized until all that could be called a cervix had been burnt off. Then about half the women having any uterine irritation had the cervix split—"incised," they called it; and then came the son of the splitter and sewed them all up, and I saw one enthusiast who, to be sure that he reached the seat of the trouble (and perhaps he builded wiser than he knew), sewed up a whole vulva. Now the women are to be spayed, and it only remains to carry out John Randolph's suggestion, and castrate the men, and the millennium will begin to dawn.

We don't hear so much of the "cockeye" and the "microcockeye" that my old English friend used to talk about, these having given place to the bacillus, who, if reports be true, is likely to distance all competitors. The frogs of Egypt "were nowhere" beside this fellow. Why didn't Moses think of him? They confined themselves to the beds, kneading-troughs, etc., but this evil beast is in our teeth, hair, and breath. He pollutes the girls' mouths and infects the honey on their lips, mustaches are tainted, and the terrible consequences of a contact between the two when owned by different individuals can better be imagined than described. We understand that the Boston girl interposes a piece of aseptic gauze at an opportune moment, and that the New York lover is constantly provided with a vial of a solution of mercuric bichloride, 1 to 2,000, which he applies freely to his mustache "before and after taking."

My personal interest in this bacillus is very great, especially as they have got him down so fine as to almost be able to bestow proper names on him, and as I have long entertained in my breast (I am not speaking poetically) a large family of consumptive bacilli, I am anxious to know what is to be done with us, as, if all the scientists say is true, our wife and children and friends ought to shut us up in a separate house and leave us to fight it out alone, as it is probable that some day some of my bacilli family may attack my other family, and in the language of the wild West, "get away" with us altogether. These bacilli have lived with me twenty-six years or more, and the most of that time I have lived with a wife and children, we all (bacilli and the others) living very harmoniously, and I know hosts of men and women who have been or are similarly affected. But if people can be convinced that we are dangerous neighbors, the question as to what is to be done with the sick is a very grave one. One plan which I have seen carried out among the Apaches is, I think, the most effectual of any that can be followed. When one of their number is sick he is put into a wagon and food and water carried to him. When he dies the house, body, and all are at once burned up. Some of the tribes I have met in Asia, when a person becomes very ill, put him in a mud house and seal it up close, and run away. We call people who do such things heathen, but in fact they are scientists of a high order, and have not learned that what they think is a demon is only a bacillus, and they are quite scientific in leaving his neighborhood.

In this civilized and Christian country, I have seen a father and mother left alone to nurse and bury children ill and dead of scarlet fever, or diphtheria, and the dread of contagion is becoming so widespread that we often see cases of simple fever shunned like a pestilence.

When cholera or yellow fever appears, how careful everyone is in the business world to avoid creating a panic.

How ill it becomes the profession, filled with the bravest and most self-sacrificing men, to say or do anything to terrorize weak-minded people who may have in their families persons the victims of pulmonary consumption. How much better to seek to inspire hearts with courage rather than fears that are well-nigh groundless.

The people soon begin to understand that doctors are saying that everything is "catching," and their selfishness needs no aid from science. The medical field has not yet become so barren of practical ideas that physicians who daily face death in the shape of yellow fever, small-pox, scarlet fever, and diphtheria, and pass by unharmed, should be spending their efforts to frighten mankind by the display of a scientific bug-a-boo.

HENRY K. PALMER, M.D.

TRINIDAD, COL.

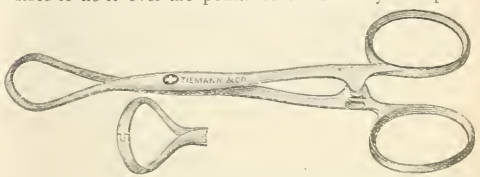
New Instruments.

A NEW CLAMP-FORCEPS, FOR SECURING AND LIGATING DEEP-SEATED ARTERIES.

BY H. W. BOONE, M.D.,

SURGEON TO ST. LUKE'S HOSPITAL, SHANGHAI, CHINA.

THE instrument here figured is intended for use in cases where the vessel is so deeply situated that it is impossible to tie it over the points of the ordinary forci-press-



ure forceps. The teeth of the instrument are rounded and they interlock so as to afford a firm grip, while they cannot tear the tissues. This is a great improvement on the teeth of the forceps in general use. It makes them excellent torsion forceps. The round head of the instrument makes it impossible to have any trouble in tying the

ligature, as the thread slips over the end of the forceps and settles into its proper place as soon as traction is made on the ends of the ligature. I have used the instrument for several years in both hospital and private practice. It has also had an extensive trial at the hands of other surgeons, and it has never failed to give entire satisfaction; thus effecting a saving of time and trouble in what has often been a most troublesome difficulty. Its form, with the French joint, makes it an easy matter to clean and keep it aseptic.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 4 to May 10, 1890.

BAXTER, JEDEDIAH H., Colonel and Chief Medical Purveyor, and WOODHULL, ALFRED A., Major and Surgeon. By direction of the Secretary of War, the above-named officers are detailed as delegates to represent the Medical Department of the Army at the annual meeting of the American Medical Association, to be held at Nashville, Tenn., May 20, 1890. The officers named will proceed to Nashville at such time as will enable them to reach there on or before May 20th. S. O. 107, par. 4, A. G. O., Washington, D. C., May 7, 1890.

VICKERY, RICHARD S., Major and Surgeon. By direction of the Secretary of War, granted leave of absence for twenty-one days. S. O. 103, par. 17, A. G. O., May 2, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 10, 1890.

GREEN, E. H., Passed Assistant Surgeon. Ordered to the Receiving Ship Dale, Washington Navy Yard.

WHITING, ROBERT, Passed Assistant Surgeon. Detached from Dale and to the Nautical School-ship St. Marys.

WHITAKER, H. W., Passed Assistant Surgeon. Detached from the St. Marys and resigned, to take effect November 5, 1890.

ROSS, J. W., Surgeon. Ordered to the Navy Yard, Pensacola, Fla.

FLINT, J. M., Surgeon. Appointed a delegate to represent the Medical Department of the Navy at the Pharmacopœia Convention to be held in Washington, D. C., May 7th.

DEAN, R. C., Medical Director, and WOOLVERTON, THERON, Medical Inspector. Appointed delegates to the American Medical Association Convention to be held at Nashville, Tenn., May 20, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 10, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	3
Scarlet fever	97	8
Cerebro-spinal meningitis	5	7
Measles	361	26
Diphtheria	90	22
Small-pox	0	0
Varicella	7	0
Cholera	0	0

The William F. Jenks Memorial Prize.—The second triennial prize of $450, under the deed of trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "The Symptomatology and Treatment of the Nervous Disorders following the Acute Infectious Diseases of Infancy and Childhood." The conditions annexed by the founder of this prize are, that the "prize or award must always be for some subject connected with obstetrics, or the diseases of women, or the diseases of children;" and that "the trustees under this deed for the time being can in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia." The prize is open for competition to the whole world, but the essay must be the production of a single person. The essay, which must be written in the English language, or if in a foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pennsylvania, U. S. A., before January 1, 1892, addressed to Louis Starr, M.D., Chairman of the William F. Jenks Prize Committee. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

Spare your Doctor.—The *Albany Press* says: "Never telephone or send for a doctor to come immediately, when you can just as well say: 'Any time this morning will do, or come as soon as it is convenient.' You may be causing others much more dangerously ill than yourself to wait unnecessarily. Furthermore, remember that every man needs one day in seven in which to rest. Spare your doctor his Sundays, if possible. No one should work three hundred and sixty-five days in the year, and consume part of the nights as well, and face the inclemency of all weathers, climates, and seasons, without having proper chance for rest and recuperation." Eminently sound doctrine. But even under these adverse circumstances the doctor would not complain if the patient did not so often forget the character of the services when the bill is sent. We should say spare your doctor, and also pay your doctor.

A Female Medical Anarchist.—One of the most brilliant, if not the most powerful, of the anarchists in New York, is said to be a woman medical practitioner, living on the east side of the town. She has been in practice about six years, and is reported by her admirers to have quite a large clientèle. Her admirers also say that she is very beautiful and a most eloquent orator.

Free Medical Attendance.—The Canton of Basle, Switzerland, has voted to provide free medical attendance and medicines to every person who may be ill and whose annual income is not in excess of $240. The State will pay the fee of the physician and the druggist's charges. They do some things in Switzerland better than we do, for here the well-to-do, equally with the poor, receive free medical treatment, if they ask for it, and the doctors get no pay for their trouble and seldom even thanks.

An Inconvenience in Pulling your own Teeth.—A dentist of Kingston, N. Y., recently pulled eight of his own teeth. He says he found it somewhat inconvenient, because he couldn't keep his head still.

MODERN METHODS OF EXAMINATION IN DISEASES OF THE STOMACH,

WITH A CONSIDERATION OF THEIR DIAGNOSTIC VALUE, ESPECIALLY IN GASTRIC CANCER, SIMPLE ULCER OF THE STOMACH, AND GASTRIC HYPERSECRETION.[1]

BY FRANCIS P. KINNICUTT, M.D.,

PHYSICIAN TO ST. LUKE'S HOSPITAL AND TO THE NEW YORK CANCER HOSPITAL, NEW YORK.

As early as 1871 Leube called attention to the advantages to be derived from the use of the stomach-tube for diagnostic purposes in diseases of the stomach. The suggestion introduced the employment of new chemical and physical methods for determining, more exactly than hitherto had been possible, the condition of the gastric secretion, as well as the activity of other functions of the stomach, in its various functional and organic diseases. Since the above date the number of workers in this new field of investigation has gradually increased, until at the present time we are in possession of a very voluminous literature, chiefly German and French, on the subject. Many of the earlier observations, based upon faulty methods and technique, were conflicting and misleading; and yet, through their reappearance from time to time in literature, they continue to obscure the positive knowledge that has been gained on many points in this interesting subject. It is my desire in the present paper to describe, as concisely as possible, those methods which continued experience has shown to be the least liable to error, and to state the conclusions which may fairly be deduced from them. My personal experience embraces nearly three hundred analyses of the stomach-contents in the past year, besides very many made during a previous period. The basis of the chemical methods employed consists in the withdrawal of the stomach-contents by means of the tube. The soft rubber tube is now universally employed, and the form used by Ewald is convenient and practical. It is open at the tip, with one large fenestra, and several smaller ones in its lateral walls immediately above, all the openings having bevelled edges. Its length should be 75 ctm., and, for use in dilated stomachs, 95 ctm. Its introduction, as a rule, is very easily effected, and no further lubrication of the tube than that produced by the saliva is necessary. In very sensitive patients it will be found useful previously to spray the posterior pharyngeal wall with a two to four per cent. solution of cocaine. Where the presence of the tube in the stomach excites much retching, the previous ingestion of a small quantity of a similar solution is advised. In cases of suspected ulcer these measures should be employed, at least in the earlier introductions of the tube. Injury to the gastric mucous membrane by the tube itself I believe to be impossible. The gastric contents are withdrawn by the "expression" method or by aspiration. The former, which consists merely in strong voluntary contraction of the abdominal muscles, sometimes fails in its object, either through lack of intelligence on the part of the patient or through insufficient contraction of weak abdominal muscles. Before considering the subject of the chemical examination of the gastric contents during digestion it is necessary, particularly in view of a discussion later in this paper on gastric hypersecretion, to refer to investigations on the conditions found in the fasting normal stomach. It has long been believed that the secretory function of the stomach is latent during the fasting period. Rosin,[1] however, as the result of examinations made in 44 fasting patients, believes this view to be incorrect. In only 2 cases could no fluid be withdrawn; in 11 the fluid contained no free HCl; in 31 both free HCl and pepsin were present in the gastric juice, although often its digestive power was apparent only after artificially increasing the HCl percentage. The amount aspirated varied between 3 and 12 c.c. Ewald and Boaz,[2] on the other hand, confirm the experience of Tiedmann and Gmelin, that, under normal conditions, the fasting stomach contains no gastric juice, and suggests that Rosin's results can be explained by the irritation of the gastric mucous membrane by a foreign body, viz., the tube, acting all the more energetically from the stomach being empty.

The results of a series of examinations kindly made for me by Dr. Norrie, of New York, in my wards in St. Luke's Hospital, would seem to corroborate the correctness of this view. Ten patients presenting no symptoms of gastric disturbance were examined. The method of procedure consisted in carefully washing out the stomach in the evening and employing aspiration the following morning, the patient fasting in the interval. The time occupied in introducing the tube and aspiration varied from thirty to ninety seconds. In two cases no fluid could be aspirated; in four cases 1½ to 2 c.c. of a neutral fluid were withdrawn; in two cases a few drops of a faintly acid fluid, containing no free HCl were obtained; in one case 2 c.c. containing free HCl, and in one case 10 c.c. with free HCl were aspirated. In two cases of anæmia, in which 2 c.c. of a neutral fluid were withdrawn at the end of one minute, 15 and 25 c.c. respectively, of a fluid containing 0.11 per cent. and 0.09 per cent. of free HCl, were aspirated by permitting the tube to remain in the stomach three and five minutes.

Test meals of various kinds have been suggested by different authors for the purpose of best judging of the chemical character of the gastric secretion during digestion. Ewald's test[3] breakfast consists of the German semmel, which is nearly equivalent to our white bread roll, and one-third of a litre of water or weak tea without sugar or milk. Chemical analysis of the semmel demonstrates the presence of albumin, sugar, starch, fat, and salts. Leube and Riegel prefer a more ample meal, the test dinner consisting of four hundred grammes of water or meal soup, sixty grammes of scraped beef, and fifty grammes of white bread. The advantages of the former consist chiefly in its greater cleanliness and in there being less likelihood of the tube becoming plugged with the partially digested remnants of food. On the other hand, the test dinner undoubtedly excites a more vigorous action of the secretory function. As one or the other variety of meal is selected, it is important to bear in mind certain rules of procedure. The same amount of food, as nearly as possible, should always be given, and the stomach-contents withdrawn one hour after the test breakfast, and between the fourth and fifth hours after the test

[3] Loc cit., p. 18.

dinner, intervals corresponding to the maximum activity of digestion after the respective meals. The basis of all practical conclusions from examinations of the gastric contents rests upon a clear recognition of the stages of the normal digestive process which follow the ingestion of one or the other of the test meals described. In repeated examinations Ewald[1] has found the chemical process after the test breakfast to be as follows (my own experience has been a similar one): After the first ten or fifteen minutes the gastric contents have an acid reaction, which is due to free acids, acid salts, or both. The free acid is lactic acid, and this predominates during thirty to forty five minutes, no reaction being obtained for free HCl by the usual methods. A stage succeeds when an appreciable amount of free HCl is present; the lactic acid gradually disappears and at the expiration of an hour the only free acid present is HCl. These stages are simply prolonged after a more abundant meal, free HCl only being recognizable at the end of the fourth or between the fourth and fifth hours. As Ewald remarks, we are not to understand by this that HCl is not secreted immediately after the entrance of food into the stomach, but rather that it exists in loose chemical combinations, and, moreover, that the presence of salts interferes with the sensitiveness of many of the reagents used for its detection. The latter only permit us to recognize the acid in a free state, and hence it is only at the height of digestion, when saturation of the albuminoids with free HCl has occurred and material for its further chemical combination is exhausted, that we may expect to find more than traces of it. The non-recognition of the difference between the *secretion* and *presence* of free HCl may be regarded as the source of many conflicting and erroneous conclusions. Any marked variation from the chemical sequence described above may be considered as probably pathological, and upon its demonstration is largely based the clinical value of chemical methods of examination. A certain system in the chemical examination of the stomach contents is desirable, and I shall therefore formulate one which I have found convenient in use.

The gastric contents being first filtered:

A. The reaction of the filtrate is determined;

B. Ten c.c. of the filtrate are employed to estimate quantitatively its absolute acidity;

C. A small portion of the filtrate is tested for free acids and acid salts;

D. A similar portion is tested for free HCl, and a quantitative analysis of the acid made if necessary;

E. Examination for lactic and other organic acids;

F. Examination for propepton and pepton.

By the above analyses we are able to determine the nature of the acidity of the filtrate, the degree of acidity, and finally the existence of peptonizing power. Further examinations consist in testing for rennet ferment, sugar, starch and its derivatives, which I believe to be seldom of any considerable practical value. A determination, however, of the actual peptic strength of the filtrate is often indicated, as we at present possess no method of estimating the pepton percentage in the gastric contents. I shall consider only those methods for determining the above points which I have found least liable to error.

B. The absolute acidity of the stomach contents is best determined by titration. Ten c.c. of the filtrate are titrated with a deci-normal solution of sodium hydrate, litmus-paper or phenophtallein[2] being used as the indicator. Under normal conditions one hour after a test breakfast, 10 c.c. of the filtrate require from 4 to 6.5 c.c. of the soda solution for neutralization;[3] values above or below this may be regarded as pathological. For the sake of simplicity these values are very generally expressed in percentages of the deci-normal soda solution; for example, by six per cent. acidity is meant that 10 c.c. of the filtered stomach contents require 6 c.c. of a deci-normal solution of sodium hydrate for neutralization. Such an acidity, if due to HCl alone, would represent 0.21 per cent. of this acid.[4] The range of free HCl in the gastric juice in normal digestion is very generally estimated at 0.15 to 0.2 per cent.

C. Leo's test[5] is a simple and convenient one for free acids and acid salts. A slip of blue litmus-paper is moistened with a drop of the filtrate and preserved for a comparison of color. To a few drops of the filtrate powdered calcium carbonate is added, and the reaction tested and compared with the original. If the litmus-paper is no longer reddened, the acidity of the filtrate is wholly due to free acids; if reddened, though less than before, the acidity is due partly to free acids and partly to acid salts.[6]

D. Examination for free HCl. In Günzburg's phloroglucin-vanillin test we possess one which is at once the most sensitive and the least liable to error of the many proposed from time to time for the detection of free HCl. Many of the color reagents employed for this purpose respond in varying degree to organic acids, and moreover, their sensitiveness to free HCl is impaired, and under certain conditions destroyed, by the presence of acid salts and albuminates in the gastric contents. These sources of error further explain many of the conflicting statements in regard to the character of the gastric secretion in disturbances of digestion. The phloroglucin vanillin solution (2 grm. phloroglucin, 1 grm. vanillin, 30 grm. absolute alcohol) in the presence of pure HCl becomes a brilliant cherry-red with the deposition of cherry-red crystals. In the presence of minute quantities of free HCl, it is necessary to heat the solution gently, preferably in a white porcelain dish, when, with evaporation of the water, a similar distinct cherry-red color appears in films or streaks at the point of contact of the reagent with the acid solution. In testing the filtrate only a drop or two of the reagent should be added to about one c.c. of the filtrate. The above reaction is not developed by organic acids, and from an extended experience I believe does not fail in the presence of albuminates or salts.

The employment of too great heat in testing may result in the development of a brown or yellowish-brown color from the combustion of organic substances, but never in that of the characteristic red color produced by free HCl. The sensitiveness of the test permits of the detection of free HCl in a dilution of 1 to 20,000.

Cahn and v. Mering's[7] method for the quantitative analysis of free HCl has been, and is still, extensively employed for this purpose. The process is a comparatively simple one. It consists in the removal of organic acids from the filtered stomach contents by distillation and ether and the titration of the watery residue. Honigmann and v. Noorden have shown,[8] however, that the acidity of this residue is not necessarily due to free HCl alone.

Sjoqvist's method demands the facilities of a laboratory.[9]

Leo[10] has very lately published a quantitative test which is apparently more exact and clinically practical. The presence of acid phosphates and lime salts, as well as organic acids, in the stomach contents is regarded. The method of procedure is as follows: 1. Remove the organic acids from the gastric filtrate by distillation and ether, and add sufficient water to the residue to restore

[1] Loc. cit., p. 21.

[2] Phenophtallein in alcoholic solution has the property of developing a brilliant carmine color in alkaline solutions and of remaining colorless in neutral and acid solutions.

[3] Ewald: l. c., p. 23.

[4] Each c.c. of the deci-normal solution of sodium hydrate contains .004 grm. of caustic soda, and will exactly neutralize .00364 grm. of absolute HCl. The test alkali is slowly added from a burette, with constant stirring, until a neutral reaction is shown by the indicator. The number of c.c. so used multiplied by .00364 expresses the percentage of HCl contained in the 10 c.c.

[5] Leo: Centralblatt f. d. med. Wissenschaft., No. 26, 1889.

[6] The reaction of acid phosphates is not affected by the presence of calcium carbonate.

the original volume; 2. Take 10 c.c. of this residue, add 5 c.c. of a concentrated solution of $CaCl_2$ and titrate with a deci-normal sodium hydrate solution until a faint red color appears, using phenolphthaleïn as the indicator; 3. Take a second convenient quantity, add several grammes of powdered calcium carbonate and filter. Take 10 c.c. of this filtrate, heat until the free carbonic acid is expelled, add 5 c.c. of concentrated $CaCl_2$ solution and titrate. The difference in the result of the two titrations will represent the free HCl value in 10 c.c. of the gastric fluid.[1]

E. Examination for organic acids. Uffelmann's test with an aqueous solution of the chloride of iron I believe to be reliable for the detection of lactic acid. The iron solution should be sufficiently weak to be almost colorless. This at once assumes a distinct yellow color in the presence of a *trace* of lactic acid. A few drops of the filtrate are added to the iron solution in a test tube, and to avoid the possibility of error I am in the habit of comparing this solution with a control iron solution. Uffelmann's carbolated chloride of iron test for lactic acid, which is so frequently used, is very unreliable, as it reacts to glucose and certain salts, especially the acid phosphates, which are present as a rule in the stomach contents, as well as to lactic acid.[2]

F. Examination for propepton and pepton. Since propepton is probably a transitional form of HCl pepsin digestion, its recognition in the gastric contents may be at times of practical value. At the maximum of normal gastric digestion only traces of it are found to exist, while pepton is present in abundance—in other words, its presence in large amounts at the height of digestion indicates a deficiency in this function. A reliable test for propepton consists in adding 2 or 3 c.c. of a saturated solution of chloride of sodium to an equal amount of the stomach filtrate, to which is added one or two drops of strong acetic acid. The propepton, if present, is precipitated. The presence of pepton is demonstrated by the so-called biuret reaction. Inasmuch as this is also developed by propepton, the latter must first be precipitated as above described and its filtrate then examined by the biuret test as follows: To 2 or 3 c.c. are added 1 c.c. of liquor potassæ and a few drops of a one per cent. solution of sulphate of copper. If pepton is present a purple-red color is developed. The chemical examination of the stomach contents by the methods described, with the exception of the quantitative analysis of HCl, is simple and practical and takes no longer time than an ordinary analysis and microscopic examination of the urine.

The chemical sequence and conditions indicated by the above-described methods in normal digestion, after the test meal, afford a basis for a recognition by the same methods, of perversions of the chemical process and the pathological conditions under which they occur They may be grouped, at least provisionally, as follows:

A. Free HCl demonstrable at the height of digestion, but apparently in diminished amount; organic acids present; peptonizing power present but diminished in degree.

B. Free HCl not demonstrable; organic acids present in abundance, usually in excess; peptonizing power sometimes present, sometimes absent.

C. Free HCl apparently increased in amount; organic acids present in small amount or absent; peptonizing power present and active.

[1] Leo's method for the estimation of the degree of acidity of a solution of HCl in the presence of acid phosphates is based on the fact that calcium carbonate is not decomposed by the latter at ordinary temperatures. Hence, provided the volatile and organic acids be removed, the loss of acidity of the gastric fluid after treatment with calcium carbonate would represent the amount due to HCl, if the presence of $CaCl_2$ in the fluid to be titrated did not determine the formation of a neutral phosphate containing calcium and thus necessitate a double equivalent of the sodium hydrate solution to combine with the chlorine thus liberated. However, the addition of an excess of $CaCl_2$ previous to each titration renders the conditions uniform and the results comparable.

[2] By treating the filtrate with ether, which absorbs any lactic acid present, and then testing a watery residue of the ethereal extract with this reagent the above source of error is eliminated.

The pathological conditions embraced in group *A* are chronic gastric catarrh, cachectic conditions produced by various diseases, certain neuroses with apparently depressed gastric innervation, pyrexia of greater or less degree.

B. Gastric cancer, chronic gastric catarrh of a severe type, atrophy of the gastric mucous membrane, amyloid degeneration of the same, toxic gastritis.

C. Simple ulcer of the stomach, secretory neuroses (exalted excitability of secretory nerves) primary and secondary.

The determination of the activity of other functions of the stomach than the purely chemical one is often of diagnostic value.

The absorptive power is best estimated by the test proposed by Penzoldt.[1] Two grains of iodide of potassium are administered by the mouth, preferably after a meal, in gelatine capsules (first carefully wiped to guard against any of the salt clinging to their outer surface) and the moment of the appearance of iodine in the saliva noted.[2] Under normal conditions iodine is detected after ten to fifteen minutes. If it appears only at the end of half an hour to an hour the absorptive power of the stomach may be regarded as diminished. It has been found to be defective in gastric catarrh, dilatation of the stomach, etc.

Several methods have been proposed for the estimation of the motor efficiency of the stomach. Of these I shall refer only to the one which I have found the least liable to error, viz., Klemperer's.[3] It consists in introducing 100 grm. of olive oil into the stomach by the tube and withdrawing what remains at the end of two hours. Oil not being absorbed by the stomach, the difference between the amount introduced and that withdrawn indicates the degree of motor efficiency. Under normal conditions the stomach discharges from 70 to 80 grm. into the duodenum in the above interval. I have not observed any clinical impracticability in this method. I have employed it in both hospital and private practice, and believe it to be the most exact of the various methods proposed. Without accepting the extreme view advanced, especially by Jaworski, that the propulsive function of the stomach is its chief one, any impairment of its motor power may be regarded as a serious symptom. Klemperer[4] believes that motor insufficiency is not infrequently the *first* symptom of gastric disease, which later develops secretory and anatomical anomalies. Its estimation is not only of much diagnostic value but also of importance in prognosis and therapeusis. In cases of hypersecretion, the preservation of motor efficiency implies the absence of ectasia and affords grounds for a more favorable prognosis. In gastric cancer, an efficient peristalsis compensates for a time at least the perversion of the secretory function. A fair nutrition is maintained by means of intestinal digestion.

It remains to describe the more purely physical methods employed in the examination of the stomach. A recognition of gastric ectasia is often possible only by artificial distention of the stomach with air. Frerichs introduced the method of evolving the gas in loco by the successive administration by the mouth of sodium bicarbonate (2–3 grm.) and tartaric acid (1–2 grm.) in solution. Runeberg[5] suggested the introduction of air by means of the ordinary hand bulb attached to the end of the stomach tube. Either method is efficient for the purpose. The latter permits of more exactly determining the amount of air necessary in the individual case, which varies very considerably; the possibility of exciting irritation of a sensitive mucous membrane by carbonic acid gas is moreover avoided. Distention of the stomach with air has sometimes enabled me to determine more exactly than was otherwise possible the site of a gastric tumor.

[2] Filter-paper is saturated with starch paste, dried, and the saliva ejected on it every five minutes. On the addition of strong nitric acid a bluish color is developed in the presence of iodine.

[3] Klemperer: Deutsche med. Wochenschr., No. 47, 1888.

[4] Klemperer: Verhandlungen des Congresses fur innere Medicin. viii. Congress. Wiesbaden, April, 1889., Seite 271–284.

[5] Runeberg: D. Arkiv f. klin. Med., Bd. 34, S. 460.

Piorry's and Penzoldt's[1] method of determining the lower boundary of the stomach, consists in the introduction of a large quantity of fluid by the tube. The lower line of dulness thus produced corresponds to the course of the greater curvature. The occasional absence of gas in the transverse colon may be a source of error in this method. An extension of the lower boundary of the stomach, below a line drawn horizontally through the anterior superior spinous processes of the ilium, may be regarded as indicating positive dilatation.

Gastrodiaphany, as it is designated by its inventor, Dr. Einhorn, of New York, consists in an illumination of the stomach from within, in a manner which permits at least of a recognition of its contours through the abdominal walls. An Edison's incandescent lamp is inserted into the tip of an ordinary soft rubber stomach-tube, the conductors being carried through the tube and attached to a storage-battery. A dark room is necessary for the examination. The practical use of this ingenious method thus far consists in demonstrating the size of the stomach.

Gastroscopy,[2] direct inspection of the gastric mucous membrane, introduced by Mikulicz, need only be mentioned to be condemned. The introduction of a tube of the size and stiffness necessary for this purpose, is painful and, in my judgment, unsafe.

The prescribed limits of the present paper permit me to consider critically the clinical value of modern methods of examination only in the diagnosis of gastric cancer, simple ulcer of the stomach, and the pathological condition known as gastric hypersecretion.

It is an interesting fact, which Ewald has referred to, that as early as 1842 Golding Bird,[3] of Guy's Hospital, concluded as the result of personal investigations, that in the progress of gastric cancer the secretion of HCl was gradually diminished, the percentage of organic acids increasing *pari passu*. The observation was forgotten, but, to-day, as the result of very numerous observations by many of the most distinguished clinicians in various parts of the world, its practical correctness has been corroborated. The secretion of free HCl undoubtedly occurs in many conditions where its presence cannot be demonstrated by the tests at present employed. Such a failure of the tests does not detract from their clinical value, however. Klemperer,[4] while admitting that free HCl is seldom present in the stomach contents in gastric cancer, doubts whether its secretion is even diminished. He believes that it is combined with organic bases. Such a combination undoubtedly occurs, and may be accepted as a partial explanation of the absence of free HCl. It is now generally conceded that gastric cancer *per se* is incapable of affecting the secretion of HCl, and by many the failure of tests to detect it in this disease is found in the existence of an associated gastritis and glandular atrophy of varying degree. Pathological lesions of this nature are present presumably only in a slight degree in the case of small and strictly localized neoplasms, and under such conditions we should expect to find the secretory function of the stomach but slightly impaired. A case corroborative of this view has been reported by Ewald.[5] In this case free HCl was present in the early examinations, and a sharply localized neoplasm was found on resection of the pylorus, the mucous membrane showing slight changes except in the immediate vicinity of the tumor. The number of published cases of gastric cancer in which free HCl has been demonstrable is exceedingly small, however. On the other hand, the number of cases in which its constant absence has been observed is correspondingly large. Of these I shall refer only to Riegel's,[6] 16 in number with 306 examinations, Rosenheim's, and to some personal ones.

In 274 analyses in 13 cases of Riegel's, free HCl was never detected. In his remaining 3 cases, a feeble HCl reaction was obtained only in the early examinations.

In 14 of Rosenheim's 16 cases,[7] no free HCl was demonstrable. In one its presence was transitory, in one hyperacidity was believed to exist. (The method used for the quantitative analysis in this case has since been found to be fallacious.)

In 8 cases under my personal observation with 4 autopsies, and in 1 under the care of Dr. Roosevelt with autopsy, with 132 analyses of the stomach contents, free HCl was demonstrable only in 2 cases. In 1 of these a trace was detected in 2 examinations out of 12, in the second a feeble HCl reaction was once obtained. In 3 of the cases not confirmed by autopsy, epigastric tumor existed, and repeated hæmatemesis had occurred. In the remaining case no tumor was recognizable, but during a period of two years there had been progressive loss of strength and flesh, and repeated hæmatemesis, vomiting, etc. The patient died of inanition several weeks after admission to the hospital. In 4 of the cases confirmed by autopsy no tumor was detected in repeated examinations during life. In 1 of these, a patient seventy-six years of age, there was an absence of all symptoms and signs referable to the stomach with the exception of complete anorexia and the failure of free HCl reaction to all tests. In the remaining case in which no free HCl was ever detected in 40 analyses of the stomach contents, always after test meals, and in which it was possible to observe the gradual diminution of the peptonizing power until the gastric filtrate was wholly devoid of peptic strength, the neoplasm was located at the pylorus. Very complete stenosis existed, however, and numerous sections of different portions of the mucous membrane, examined by Dr. Thacher, the pathologist of St. Luke's Hospital, showed the presence of a chronic gastritis with glandular atrophy. The anatomical changes varied greatly in degree; in some of the sections no tubules were recognizable, in others they were numerous; small cell infiltration and increase of connective-tissue was observed in all sections. There was no regularity in the distribution of the anatomical anomalies. The autopsy was made about six hours after death.

A localized neoplasm, causing pyloric stenosis, may be expected to excite ultimately a chronic gastritis with or without glandular atrophy. The following conclusions, from investigations up to the present time, seem justifiable:

The diminution or absence of free HCl in chronic gastritis, atrophy of the gastric mucous membrane, and certain other diseases previously mentioned, detracts from the positive value of this sign in the diagnosis of gastric cancer. It is rather to be considered of corroborative value in the presence of other symptoms and signs of the disease.

On the other hand, *the presence of free HCl in the stomach contents, in repeated examinations, in doubtful cases, is of the greatest diagnostic value, and points very certainly to the absence of cancer.*

Simple Ulcer of the Stomach.—The character of the gastric secretion in simple or round ulcer of the stomach has been the subject of numerous investigations. Riegel[8] has published the results obtained by him in 382 analyses of the gastric contents in 42 cases of this disease. In all the free HCl percentage at the height of digestion was found to be abnormally high. Values of 0.4 to 0.5 per cent. were frequently found. His experience leads him to conclude that hyperacidity is a constant factor in gastric ulcer; that, although it is not necessarily followed by ulcer, it may be regarded as a predisposing cause.

Rosenheim,[9] in 8 cases was able to demonstrate the presence of hyperacidity in only 2; in 4 cases the HCl percentage was within normal limits, in 2 it fell somewhat below. Very lately[10] Rosenheim has published 4

additional cases of ulcer complicated with cancer of the stomach. In all, free HCl was present in the stomach contents, in 2 hyperacidity existed. In the 3 cases in which the diagnosis was confirmed by autopsy, the HCl disappeared from five months to several weeks before death.

In 4 consecutive cases presenting characteristic symptoms of this disease (typical gastralgia, repeated hæmatemesis, etc., extending over a long period) personally observed during the past few months, free HCl was found in all the examinations, 31 in number, of the stomach contents after a test meal. Its percentage in all fell within nearly normal limits, 0.17 to 0.23 per cent. In one case previously observed, in which the autopsy revealed an ulcer the size of a twenty-five cent piece, lying partly within the pylorus and causing extreme stenosis both by hypertrophy of the immediately contiguous structures, and by adhesions of the pylorus to the under surface of the liver, hyperacidity was constantly present.

Observations by Cahn, v. Mering, Ritter, and many others also would indicate that hyperacidity is not a *constant* factor in simple ulcer. Ewald[1] suggests that Riegel's dictum should be modified as follows: "In gastric ulcer there is secreted a juice constantly containing free HCl and generally in excess."

The constant presence of free HCl, either in normal or increased amount, in simple ulcer of the stomach may justly be regarded as a sign of great clinical value in a differentiation between this lesion and gastric cancer. Especially is this the case in a differential diagnosis between ulcer of the pylorus and cancer occupying the same site. In the former instance the anatomical changes excited in the tissues immediately contiguous to the ulcer, and the not infrequent existence of adhesions, may give rise to an induration recognizable by palpation, and to pyloric stenosis of varying degree. In two cases of ulcer of the pylorus personally observed during the life of the patient, the diagnosis being confirmed by autopsy, a small tumor was easily recognizable and marked stenosis existed.

In cases of cicatricial stenosis from ulcer a tumor also may be present. It existed in three cases personally observed in which the diagnosis, confirmed by autopsy or surgical operation, was chiefly based upon the presence of free HCl in the stomach contents.

In conclusion, the presence of free HCl in the gastric contents in repeated examinations, in cases of the nature described above, *strongly points to the non-cancerous character of the lesion.*

Gastric Hyperacidity and Hypersecretion.—The term hyperacidity is commonly used by modern writers to denote an increase in the normal production of free HCl during the act of digestion; hypersecretion to indicate a periodic or continuous secretion of the gastric juice independently of the ingestion of food. To Reichmann belongs the credit of first demonstrating by exact methods the existence of secretory disturbances of this nature. His investigations have been supplemented and corroborated by those of Jaworski, van den Velden, Riegel, Klemperer, and others. Their conclusions, although differing somewhat in details, may be summarized briefly as follows: Aside from the association of hyperacidity with gastric ulcer, hyperacidity and hypersecretion apparently occur both as idiopathic neuroses of the secretory nerves of the stomach and as secondary affections in other neuroses. Hyperacidity frequently exists independently of hypersecretion; hypersecretion, on the other hand, is as a rule accompanied by hyperacidity. Hyperacidity and hypersecretion occur in both a periodic and a continuous form; in periodic hypersecretion the acidity often is not increased. Hypersecretion ultimately is very generally followed by atony of the muscular coat of the stomach (motor insufficiency) with all its attendant evils. Jaworski[2] believes these secretory disturbances to be of very common occurrence. He found hypersecretion in 121 out of 222 gastric cases examined, and in 115 of the 121 there was associated hyperacidity. Jaworski includes all cases under the head of hypersecretion in which more than 10 c.c. of gastric juice can be aspirated from the fasting stomach. Riegel's[1] investigations also indicate the frequent existence of hypersecretion. Ewald,[2] on the other hand, in 600 patients observed this condition only fifteen times. He states, however, that he is incompetent to speak authoritatively on the subject, as he has examined for hypersecretion exclusively in those cases presenting its most characteristic symptoms. My own experience, with similar limitations, is closely in accord with Ewald's. Inasmuch as the question of the condition of the fasting stomach is still *sub judice*, in order to avoid any possible error I have fixed as high a limit as 50 c.c. of gastric juice as a basis for a diagnosis of hypersecretion. I have been able to demonstrate it in three patients whose symptoms suggested its existence. Its early recognition is very desirable, as by appropriate treatment the sufferings of the patient can be greatly relieved and the affection itself possibly controlled. The history and symptoms of a patient are of assistance in a diagnosis of hypersecretion, but positive proof of its presence is furnished by modern methods of examination. Hyperacidity and hypersecretion have been observed in cases of melancholia, hysteria, neurasthenia, and in other neuroses; hyperacidity as a temporary symptom in the gastric crises of tabes dorsalis, and as a transient symptom accompanying or following the passage of gall-stones and renal calculi. The symptoms are of a nature to be expected from an irritation of the gastric mucous membrane by a hyperacid secretion. They are epigastric sensitiveness and pain, pyrosis, and eructations; if the hypersecretion has been of long standing the symptoms and signs of gastric ectasia are superadded. The tongue is usually clean, the appetite is rarely diminished and is frequently increased; there is often excessive thirst. The pain, which usually begins at the height of digestion and continues during the fasting period, is frequently very acute and paroxysmal, the patient often crying out in the attacks, and assuming a sitting posture with the body bent forward. Relief is often obtained by the ingestion of warm fluids, particularly milk, but not infrequently only by the use of opium. The digestion of carbo-hydrates is delayed, while that of the albuminoids is rapidly effected. In the early stages the general nutrition is usually unimpaired, though anæmia is often present. Suggestive as the above symptoms are of hypersecretion, a positive diagnosis is only possible by the following method of examination: The stomach should be washed out, preferably in the evening, and the tube again introduced the following morning, the patient fasting in the interval, and expression or aspiration employed. If hypersecretion is present, a clear or more or less turbid fluid, colorless, or more commonly of a greenish or greenish-blue color, sour smelling, of a strongly acid reaction, and varying in amount from 50 to 1,000 c.c., is withdrawn. This fluid, in the absence of any fragments of food, is devoid of organic acids and pepton, usually contains free HCl in larger amount than normal gastric juice, and digests coagulated albumin rapidly—in brief, it is hyperacid gastric juice. The following case furnishes a typical example of this disease.

E. H——, aged fifty-eight, dressmaker, admitted to St. Luke's Hospital, October 7, 1889. *Previous history:* Good health until four years ago. Digestive disturbances since. For the past eighteen months epigastric pain and distress, appearing about four hours after meals, relieved at first by voluntary vomiting. The vomited matter rarely contained food, was copious, acid, and had the appearance of dirty water. For the past eight months the attacks of pain have been very acute, and unrelieved by vomiting, and have occurred as frequently during the night as during the day. Partial relief was obtained by the frequent ingestion of large quantities of warm water or milk, sometimes by lying on the stomach, frequently

[2] Ewald: Loc. cit., p. 423.

only by the use of some medicine the nature of which is unknown. The patient was incapacitated for work.

Condition on Admission.—The above described symptoms were present. Physical examination of the heart, lungs, and liver was negative. The spleen was slightly enlarged. The examination of the urine was negative. Examination of the blood: red blood corpuscles, 4,131,250 per cmm.; hæmoglobin percentage, 44. The stomach was dilated; the lower boundary, both by inflation and by the water test, was recognizable on a level with a horizontal line one and a half inch below the umbilicus. Its absorptive power, determined by the iodine test, was nearly normal. Its motor power was diminished — two hours after the introduction of 100 c.c. of olive oil 60 c.c. were recovered. One hundred and thirty c.c. of a slightly turbid, greenish, highly acid fluid were withdrawn by aspiration from the stomach in the morning, careful lavage having been employed the previous evening, the patient fasting in the interval. The fluid contained no organic acids, acid salts, or pepton; it digested coagulated albumin rapidly; free HCl (0.23 per cent.) was present. During a period ending January 1st, thirteen examinations of the contents of the fasting stomach were made with very similar results. The amount of gastric juice withdrawn varied from 75 to 130 c.c. on different occasions; the percentage of free HCl was always above normal. Daily lavage and large doses of sodium bicarbonate, given systematically after meals, and repeated in two hours, gradually procured entire immunity from the attacks of pain, and the patient gained slowly in weight and strength. The degree of hypersecretion varied but slightly, however. In the latter part of January the patient suffered from a very severe attack of zoster. From this date until her discharge from the hospital, on March 25th, 26 examinations were made; 13 of the contents of the fasting stomach, 13 of its contents after a test meal. In 7 of the former the fluid gave a neutral or alkaline reaction, in 6 it was slightly acid, containing 0.06 to 0.08 per cent. of free HCl. The amount of fluid obtainable by aspiration varied from 48 c.c. to (on one occasion) 115 c.c. The patient continued to be free from all epigastric pain and distress, and was discharged, having gained nine pounds in weight. All medication was dispensed with during the last month of residence in hospital. Daily lavage was, however, employed. The percentage of free HCl in the gastric contents, after a test meal, from March 1st, was never above normal. The final disappearance of hyperacidity nearly coincidently with the development of the zoster, the medication in no respect being changed, is an interesting fact.

In a second case of hypersecretion with gastric ectasia, under my observation, the sufferings of the patient, which were very acute, were temporarily relieved by a similar method of treatment. The patient left the hospital too soon to judge of its further results. A third case is still under observation. The patients whose cases have been referred to were all of a distinctly neurotic temperament. Modern methods of investigation in diseases of the stomach are fairly entitled to the credit of a demonstration of a pathological condition which previously had only been suspected.

The purpose of the present paper has been fulfilled if the most exact and practical of these methods have been clearly described and their true value for diagnostic purposes indicated. Their value in suggesting a more exact therapeusis has only been incidentally referred to.

In conclusion, I desire to express my indebtedness to the gentlemen of the house staff of St. Luke's Hospital, Drs. Van Horne Norrie, Colman Cutler, and Levi Warner, and to Dr. Robert Devlin, of New York, for their efficient assistance in my investigations.

The Dr. J. M. Da Costa Association is the name of a new society organized by the Philadelphia graduates of the class of 1890 of the Jefferson Medical College.

TUMOR OF THE BRAIN (THALAMUS AND INTERNAL CAPSULE).

By ROBERT T. EDES, M.D.,

WASHINGTON, D. C.

Dr. G——, aged forty-two, who had led from boyhood a very active and responsible life, and who had been for nineteen years carrying on a laborious practice in the western part of Maryland, came to Washington, in November last, for advice and treatment.

The following account is condensed from his letters to his friend Dr. W. K. Butler, of Washington, and subsequent examinations by Dr. Butler, Dr. D. W. Prentiss, and myself.

He had usually been healthy, with the exception of typho-malaria in 1867, and of sick headaches. There was no constitutional infection of any kind. He used no stimulants or tobacco.

In the spring of 1889 he "went to pieces fast," had an attack of nearly complete suppression of the urine, with albuminuria and swelling of the legs, which symptoms, with the exception of the first, apparently lasted for some time, but disappeared during the summer.

The exact date at which the symptoms connected with his last illness began cannot be exactly determined, and was perhaps unknown even to himself.

It was probably, however, in June. At this time his right side began to "feel asleep." He describes it afterward as "heavy as lead, with loss of feeling almost general from crown of head to sole of foot;" his "face felt like a piece of leather."

The right side was worse when the weather was cold, and was relieved by heat. He found "no feeling or contraction of muscles" on the affected side from magneto-electricity, although very marked on the left.

He speaks elsewhere of "numbness all over the body, but worse on the right;" but also, again, of "hyperæsthesia of the rest of the body," or "nervous tension." These feelings are aggravated by brain-work or excitement, and are often so trying as almost to prevent him from carrying on a conversation, but when quiet or alone are less annoying.

He suffered from headache and "dulness of the mental faculties," and an indescribable feeling of helplessness; but it is fair to say that his letters during this period are clear and correct in spelling, grammar, and choice of words, and, with the exception of frequent expressions of fatigue, might have applied to another person. The handwriting is clear, even, and without tremor.

No choreic movements were at any time noticed. There was at times forgetfulness of the names of persons and things, but apparently not sufficient to be called amnesic aphasia of a typical kind.

Some weakness of the right side appeared, which was more noticeable to himself than to any one else.

Diplopia, or "difficulty of focussing his eyes," was noted. It was worse when he was fatigued, and relieved, like some of the other symptoms, by rest, a full meal, or a dose of sulphate of magnesia.

He had one or two attacks of nearly complete unconsciousness.

Sometime in September or October he had severe pain in the stomach after eating, which continued at intervals up to the time of his coming to Washington. Gastritis was suspected.

On November 10th the patient was sleeping heavily, so that he could not be roused. He had been vomiting so persistently for some days as to lead to the suspicion of organic disease of the stomach.

Examinations made after he had returned to consciousness showed his manner to be sluggish and dull, but no delirium. He recognized persons, answered questions intelligently but slowly, and as if fatigued by the labor of thinking as well as of talking.

He said his head ached, but he was not much inclined to complain of it unless questioned.

There was a slight but distinct right facial paralysis, involving the muscles of the angle of the mouth rather than those of the eyelids. No paralyses of the muscles of the eyeball.

His handwriting at this time, in marked contrast to that of the letters, was uneven, irregular as to the direction of the lines and the size and shape of the letters, with some tremor or, rather, uncertainty of aim, and executed with hesitation and difficulty; but there was no misspelling.

He could perform all movements asked for with hand or foot, could stand on either foot, and stand with eyes shut. Whether sitting or lying he used either hand indifferently for any desired movement, and apparently alike.

There was, however, loss of power on the right. Deep reflexes normal.

The mental condition did not permit a careful examination in regard to tactile sensibility, but there was certainly decided anæsthesia on the right, but not complete.

The field of vision could not be determined, but the vision appeared good, and was certainly not sufficiently impaired to excite his remark. There was no optic neuritis. The pupils were equal, and reacted to light and to atropine readily.

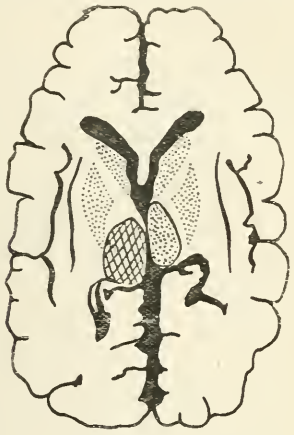
From this time until his death there were several attacks of deep somnolence from which he could not be roused, in which his pulse became very rapid and feeble, and his general condition alarming.

During these it was distinctly noticed that such voluntary movements as were made were executed almost entirely by the left side.

In other words, when he was in the somnolent condition the hemiparesis, which at other times was hardly, if at all, perceptible, became very well marked.

He lost flesh and strength, and began to pass urine and fæces in bed, even after he was able to make a coherent but short and sluggish reply to a question. Hiccough was a very annoying and exhausting symptom for two or three weeks before death. It had been present before he came to Washington for a considerable time. Constipation was marked most of the time, and occasionally the symptoms seemed to improve when it was relieved; but at other times restoration from the somnolent condition took place without any movement of the bowels having preceded it. The urine was examined with unimportant results. The treatment consisted in iodide of potassium in increasing doses, and for a few days bichloride of mercury. He died on December 13th.

The autopsy, three hours after death, was confined to the head alone. The surface of the brain was dry and the convolutions flattened, especially upon the left side. There was an excess of serum in the right lateral ventricle, but nothing else abnormal was found until a section, carried through the left thalamus, disclosed a pinkish tumor of rather soft consistency. The left hemisphere was placed in alcohol, and the tumor more thoroughly examined after hardening. On the ventricular surface the thalamus appeared simply enlarged and prominent, and to have pushed the nucleus caudatus slightly forward. On section, perpendicular to the ventricular surface, a thin layer of homogeneous, somewhat dense, gray matter (thickened ependyma) covered the rather friable brownish tumor. In the portion near the ventricle were a few small cysts containing fluid. Nearly the whole thalamus, except a small portion anteriorly and superiorly, was involved in the morbid growth. Its dimensions were: longitudinal, 5.7 ctm.; lateral, 2.5 ctm.; vertical, 5.0 ctm. Posteriorly and inferiorly the tumor was bounded by the corresponding horn of the ventricle. It compressed a little, but did not involve, the hippocampus. Anteriorly there was no distinct line of demarcation, though the transition from the diseased tissue to the normal was not a wide one. Above and anteriorly there was a little normal thalamus left. The tumor seemed to involve the posterior part of the posterior limb of the internal capsule. Externally it reached within half a centimetre, more or less, of the cortex, and was bounded by a moderately distinct line of demarcation, but no capsule. The corpora quadrigemina were unaffected. The external corpus



Horizontal Section through Basal Ganglia; corresponding to Dalton's Series B, Plate VII.

geniculatum was not identified, but the internal was closely underlaid by the morbid structure, although itself perhaps not actually encroached upon.

Sections of the tumor made and examined by Dr. W. M. Gray, the skilful microscopist of the Army Medical Museum, show that it is in reality a glio-sarcoma.

It will be seen that the salient points in this case were not numerous, but sufficiently distinct to justify a probable diagnosis of a tumor of the left brain, occupying a region either anterior to or behind the motor region, and probably the latter. Tumors situated so definitely and almost exclusively as this in the thalamus, and having so nearly destroyed it, are not common. Sometimes from their small size they cause only slight symptoms (and occasionally none at all sufficient to attract attention), but more frequently before death occurs they have invaded neighboring ganglia to an extent which diminishes their conclusiveness as physiological data.

The case here detailed has a tendency to show that the functions of the thalamus itself, the surrounding parts being comparatively unaffected, are not of such a character that their loss produces very obvious symptoms. In this case they are such that, with our present knowledge of the internal capsule, we are warranted in ascribing them rather to the limited lesion of this great conducting path ("sensory crossway") than to the ganglionic lesion. The most marked function, on the other hand, which is sometimes assigned to the thalamus, namely, that of being very closely connected in some way with vision, was, so far as could be judged, very slightly, if at all, interfered with, and was certainly not destroyed, or at all nearly so. The lesion, however, must have come very near to the part of the capsule where it would interrupt the fibres coming from the visual centres in the occipital lobe, but evidently had not actually done so.

The earliest, most distinct, characteristic, and most persistent phenomenon was the numbness, heaviness, and anæsthesia of the right side, and is fairly attributable to the involvement of the posterior part of the capsule.

The right hemiparesis, usually completely unnoticeable, or, at most, betraying itself only by slight traces in the face, but becoming very well marked during the somnolent condition, is probably to be connected with the varying conditions of pressure upon the anterior part of the capsule owing to the differing conditions of the circulation. This intermittency has been noted in other cases of tumor in this region.

The relations of the thalamus to vision are certainly not easy to make out, so far as cases of tumor go. In some, as well as in this, vision is distinctly stated to be entirely unimpaired, while in others hemianopia is noted. In others, still, we must infer the absence of hemianopia from the completeness of the report and the thoroughness of the observer.

It is to be regretted that a more careful examination in this direction could not have been made in our case before the mental faculties became too clouded; but it is certainly fair to suppose that at a time when the patient was able to notice diplopia and "inability to focus the eyes," and to observe the connection of this symptom with his general condition of fatigue, and also to note and describe the pulse, temperature, and tongue of a patient (October 14th), such a symptom as hemianopia or marked amblyopia could not have been entirely unnoticed.

Of the three most important general symptoms of cerebral tumor—headache, vomiting, and optic neuritis—only the first two were present.

Somnolence is likely to be an important symptom in tumors of the thalamus, since in this region, from its central situation, any enlargement produces a general and equable pressure in every direction. It may also easily happen that from the encroachment of the tumor on the aqueduct of Sylvius (iter à tertio, etc.) the accumulation of fluid will add to the generally diffused pressure. This, however, had apparently not taken place to any considerable extent in this case, although there was some excess of serum in the right ventricle.

The following cases, from among a much larger number examined by the aid of the "Index Catalogue of the Surgeon General's Library," resemble this here reported with sufficient accuracy to make them valuable for comparison. It is well known that observations of tumors limited, or nearly so, to the thalamus are not numerous.

They are introduced partly to show some other points of resemblance, but chiefly in reference to the question of the connection of the thalamus with vision.

Several others of a positive character, *i.e.*, where hemianopsia or crossed amblyopia was known to exist with a lesion of the posterior third of the thalamus, might have been added and may be found in Nothnagel;[1] but there are very few which show this coincidence in which it is clear that nothing beside the thalamus was involved. Nothnagel admits only two as conclusive; one by Remy, of crossed amblyopia (so reported, although it is thought possible by Nothnagel that it was really hemianopia), where the lesion was an old clot in the postero-supero external portion of the thalamus; and the other by Hughlings Jackson, of well-determined hemianopia, with a lesion which is very distinctly defined as not going beyond the thalamus.

On the other hand, there are a number where the posterior extremity was involved where vision is stated to have been good. Nothnagel says (1879) that disturbances of vision "can" exist with a lesion of the posterior third of the thalamus. Gowers,[2] nine years later, uses the words "may cause," but says, a line or two further on, that "hence we must regard the pulvinar as the intermediate visual centre."

I have not been able, among the cases published since, to find any which will bear such a criticism as Nothnagel subjects the earlier ones to, sufficiently well to justify the stronger expression of Gowers. It is certainly difficult to see how visual messages could have been transmitted through a way-station so hopelessly disorganized as the thalamus was in many of the cases to be reported, or in this one just described, sufficiently well for neither the patient nor such observers as Ferrier and Nothnagel to be aware that something was the matter with vision.

The first two cases, those of Webber and of Bruzelius and Blixt, are apparently somewhat in favor of the connection of thalamic disease and defect of vision; but the conclusiveness of the first is destroyed by the explanation of the sensory and motor phenomena given by the reporter himself, while the second is lacking in a clinical point of view. At the most, their value is better expressed by "may" or "can" than by "must."

Case I.—Webber:[3] Headache, attacks of unconsciousness (brief), right hemiplegia, right hemianopsia, right hemianæsthesia, with hyperalgesia, disturbance of speech, left amblyopia, tumor in region of optic thalami and corpora quadrigemina.

The posterior inferior part of the the right optic thalamus, in the immediate neighborhood of the corpora quadrigemina, was occupied by a nodule about the size of a filbert meat, of a red color, and rather soft consistency. The anterior corpus quadrigeminum was probably indicated. What was supposed to be the left optic thalamus was occupied through its whole middle and posterior portion by a soft red mass, like that seen in the right thalamus, and which was probably continuous with the latter. Altogether the mass must have been the size of a small plum.

Dr. Webber says the disturbance of sensation and the partial loss of motor power were probably caused by pressure of the tumor upon the posterior part of the internal capsule. Why not also the hemianopia?

Case II.—Bruzelius and Blixt.[4] Headache, weak-mindedness, formication in extremities, double vision, weakness in left (?) extremities, slight facial paralysis on the right side. Improvement with iodide. Sudden death. Hearing and vision diminished. Hen's egg tumor starting from left optic thalamus; ventricles distended with clear fluid.

Case III.—Hjelt.[5] A cholesteatoma the size of a hen's egg took in the whole of the left optic thalamus and stretched the horn of the left lateral ventricle and surrounded the choroid plexus. There were no symptoms. The patient died of cancer of the stomach.

Case IV.—Nicaise.[6] Woman, aged forty-eight. Headache left side, vomiting. Motility and sensibility intact. No trouble of vision, audition, or smell. A little incoherence, then delirium, coma, involuntary micturition and defecation. Convulsions more marked on the left side of the face. Ellipsoid tumor of the whole optic thalamus and corpus striatum of the left side, which were "totally" invaded.

Case V.—Ogle.[7] Girl, aged nineteen. Complained two or three days of sickness and headache. Drowsiness, no delirium or paralysis or alteration of pupils. Nothing said of vision. Died comatose. Left optic thalamus three times its usual size, encroaching greatly on right lateral ventricle; septum pushed forward, right thalamus pressed upon; other optic thalamus softer than natural, but nothing more.

Case VI.—Kerschensteiner.[8] Teacher, aged twenty-five. Severe headache; later vomiting. Senses completely unaffected. Pupils react, although sluggishly; cannot bear long looking at light. Some paralysis of left cheek muscles, but no other hemiplegia. The right ventricle contained four ounces of serum. A growth (soft, vascular glioma) had taken the place of the right thalamus; it was very difficult to separate from the brain substance, especially at the outer border.

Case VII.—Nothnagel.[9] Boy, aged thirteen. The face on the right side moved but little during any emotional manifestation, but at rest or for voluntary movements the paralysis was less marked. Diminution of sensation and motion on left. Gait staggering. The field of vision was not examined, but the patient could see, although the movements of the eyeball were somewhat restricted and he had choked disks. There was hydrocephalus internus and a glioma of the right optic thalamus, the lateral and posterior portions in particular being

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 24, 1890.

CHRONIC RHEUMATIC SORE-THROAT.

IN 1887 Dr. E. Fletcher Ingalls described an affection under the above name. He stated that it was a new disease in the sense that although it had existed for a long time it had not been recognized under its true characters by clinicians. The definition of this disorder as given by Dr. Ingalls (*Journal of Laryngology and Rhinology*, April, 1890) is as follows:

It is a painful affection of the throat, chronic in character, but varying much from time to time in severity, and attended by only slight physical changes in the parts involved. It usually affects the larynx, and therefore it has been described as rheumatic laryngitis; still, in many cases, it involves the fauces, the hyoid bone, and, possibly, the trachea, and it sometimes does this without involving the larynx at all; therefore the term chronic rheumatic sore-throat is preferable. It is comparatively frequent, occurs mainly in the spring or fall, and attacks adults. It usually comes on insidiously.

The patient complains of a localized pain, which is frequently referred to the cornu of the hyoid bone, and more often on the right than on the left side. Next in frequency it is felt in the larynx, generally upon one side only. It may be felt, however, in the trachea, the tonsils, and sometimes in the side of the base of the tongue. This pain is increased by pressure in nearly all cases, perhaps in all, and it may be increased by phonation or deglutition, but it often completely disappears while the patient is eating. In any case it is liable to shift its position from time to time, though frequently it is persistent for a long period in one locality. Sometimes, instead of an actual pain, the person will complain simply of a sensation of fulness or swelling of the part, or a feeling of dryness, itching, or burning; or it may simply be a sensation of discomfort which he cannot well describe. Usually the voice is not affected, but it is common for these patients to complain of fatigue after using it a short time. We find no constitutional symptoms, no fever, and the pulse is not quickened excepting from alarm. Usually there is no cough, but in some cases, especially where the larynx is involved, a hacking and annoying cough is a symptom. The digestive organs may act perfectly, but ordinarily we find the tongue more or less covered with a white or yellowish-white coating.

There may be some congestion of the parts, but this is not constant. The diagnosis is based on the uncomfortable sensations of pain, which change usually with the weather, a rheumatic diathesis, and absence of physical signs. Pressure usually increases the pain. The treatment consists in anti-rheumatic remedies internally, sedative and stimulant sprays, and hygienic measures. The most benefit has been derived from extract of phytolacca, gr. ij. to gr. iv., with salol and a laxative. Locally the application giving most relief has been a solution composed of morphine, gr. iv.; carbolic acid and tannic acid, each, gr. xxx.; and ʒ iv. each of glycerine and water.

ANOTHER FORTY DAYS' FAST.

SIGNOR SUCCI, who is gaining the reputation of being a "hunger virtuoso," has just completed a fast of forty days in London. The medical journals of that city credit him with the genuine performance of the feat. Signor Succi has done no more than our own Tanner, but he has been subjected to a more careful physiological study, and he has shown that a forty days' fast is possible to more than one human being. During the last days of his fast Succi lost about half a pound a day, his temperature remained normal, but his pulse was more than ordinarily rapid. The lesson of Signor Succi's experiment is one that has often been taught before, and it is that people eat too much, and, in this country, at least, drink too little. More diseases come from excessive and intemperate feeding than from alcohol, for wrong feeding is the basis of gouty, rheumatic, diabetic, and obese diatheses, as well as of an infinite number of gastro-intestinal ills.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

THE Forty-first Annual Meeting of the American Medical Association, which has just closed its sessions at Nashville, deserves to be recorded in the history of the Association as one of its most successful meetings. The attendance was not large, though perhaps up to the average; the representative men of the profession (those of the Northwest and South, as well as those of the East) not being present in their usual numbers. There was nothing epoch-making in the scientific work of the sections; but there was such a warm Southern welcome from the citizens of Nashville awaiting the members of the Association individually, as well as collectively, that the meeting was felt to be a success from the start. There were, as always, several public entertainments, but it was in the private receptions, of which there were three or four each evening, that the delegates were made acquainted with the citizens of Nashville, and learned how deserved is the reputation for hospitality which that beautiful city enjoys. The weather was perfect, and everything seemed to conspire to make the meeting one of the pleasantest, if not the most scientific, in the annals of the Association. There were no discussions in the general sessions which could arouse any ill-feeling, the nearest approach to such being caused by a motion to review the acts of the Publication Committee. The threatened trouble was, however, averted by a plain and temperate statement from Dr. N. S. Davis, for six years editor-in-chief of the *Journal*, of the impossibility of meeting the approval of everybody in the conduct of the official organ.

The Rush Monument Committee made its usual report, and despite past discouragements, expressed the determination to begin the erection of the monument in Washington during the quadricentennial year, though it did not explain what the immediate relation might be between the discovery of San Salvador by Columbus and the life and labors of Dr. Rush. However, we wish the committee the complete fruition of its hopes, and to this end we would urge upon our readers, whether active members of the Association or not, the duty of subscribing each his dollar to the monument fund. The Association has almost uniformly made a wise choice in the selection of its presidents, and the selection of Dr. Briggs, of Nashville, to preside over its deliberations next year, offers no exception to this rule.

ANTIMONY IN LOCAL INFLAMMATIONS AND TYPHOID FEVER.

Few drugs have had their value so fiercely contested as antimony. It was the cause of serious professional differences in the seventeenth century, when Patin attacked it with all the power of his wit and irony. It continued to be extensively used, however, and often in extraordinarily large doses (℥ j.). One of the most successful of homœopathic physicians, the late Dr. Gray, is reported to have said that if he had to choose but one word for his obituary, it would be "antimony."

It is said that the father of our country, Washington, was a firm believer in antimony, having felt that his life was saved by James's Powders in the early part of his career.

The physiological and clinical studies of modern times, however, have all tended to throw the drug into disrepute, and Nothnagel and Rossbach assert that its sole value is that of an emetic.

Surgeon-Major E. Lawrie, however, has recently come forward in *The Practitioner* as an advocate of antimony, especially in inflammations. Dr. Lawrie quotes the experience of Dr. Kent Spender, of Bath (*The Practitioner*, March, 1885), which was to the effect that tartar emetic in small doses (gr. $\frac{1}{6}$ every one or two hours) had the power of completely dissipating early local inflammations. Acting on Dr. Spender's suggestion, the treatment of surgical inflammation by antimony in small doses, frequently repeated, was commenced in the Afzalgunj Hospital in May, 1885. Dr. Lawrie has gradually extended its use, and has now come to look upon it as one of the most valuable drugs we possess, and as useful in local inflammations as quinine is in malarious fever. It prevents and arrests inflammation, if this is not originated or kept up by a specific or septic cause. It may be given, the writer says, without fear of causing nausea and diarrhœa or depression, even in diseases where its use would appear to be contra-indicated. For example, during the last year it was employed with unfailing success in mucous enteritis, which is of all diseases the most fatal to children in the plains of India. In these cases it arrests the diarrhœa and fever when nothing else will.

Dr. Lawrie adds that of late he has employed it in the treatment of typhoid fever, and has found that it cuts the disease short with such certainty that it almost appears doubtful whether the lesion of typhoid is specific or is not rather incidental or adventitious. In typhoid fever, no less than in mucous enteritis, the diarrhœa depends upon an inflammation of the intestine, and though at first sight it might be thought that antimony would increase the diarrhœa, it actually stops it, for the simple reason that it arrests the inflammation which causes it.

Dr. Lawrie's assertions are striking, and will no doubt be received with some hesitation. Still they are based upon five years' experience in both hospital and private practice, and they deserve some attention. We infer from a note that he prescribes the drug in doses of ♏ x. or ♏ xv. of the wine of antimony every hour or two.

ELECTRICITY AND THE HUMAN BODY.

The sudden death of another person by the alternating arc light current calls attention again to the effects of electrical currents upon the body, and the somewhat acrid disputes which have arisen in connection therewith. An important contribution to this subject was recently made to the Institution of Electrical Engineers by Dr. Arthur Harris and Mr. H. Newman Lawrence. The authors (*The Lancet*) conducted a series of experiments for the purpose of arriving at some numerical expression for this comparative physiological efficiency of the two forms of electric current. Their experiments embrace two classes of observations. The first are purely electrical, and go to show what is the resistance which the human body, considered as a conductor, presents to the passage of a current of either kind.

They found that the resistance of the body to continuous currents was, with good contact, seven times greater with continuous currents than with alternating. With poor contact the resistance to continuous currents was nine times greater than to the alternating current. These facts, if substantiated, would explain the well-known greater effects of alternating currents upon the human body, though they make the difference between the two much more than it really is, especially for currents that have been flowing for a time.

The second class of experiments dealt with the physiological effects of the two currents upon the human body. An elaborate series of sensation tests was made, but their value was strongly disputed by the members of the Institution.

Anniversary Dinner of the Hospital Graduates' Club.—The fifth anniversary dinner of this club was held on the evening of May 15th, at the Hotel Hungaria. The president, Dr. A. B. Townsend, was toast master. Dr. E. T. Doubleday, in the address of the evening, gave the humorous side to the struggles of the young practitioner, and was followed by Dr. R. W. Amidon, who discoursed in like vein upon the uses and abuses of electricity in therapeutics. The champion humorist of the club, Dr. J. S. Hawley, recited one of his characteristic poems. The other toasts of the evening were responded to by Drs. George F. Shrady, George H. Fox, Robert W. Taylor, A. E. M. Purdy, J. E. Janvrin, S. Baruch, W. R. Birdsall, and P. H. Ingalls, of Hartford, and lastly, the story-teller of the club, Dr. E. M. Culver, showed how well-founded was his reputation by appreciatively roaring responses he elicited.

News of the Week.

Advertising Patent Medicines in a Novel Way.—At the Methodist Annual Conference in Bath, Me., the report on printing showed the minutes printed at ten cents per copy. Objection was raised to an advertisement of Jamaica ginger, many of the members maintaining it to be an intoxicant. Bishop Andrews was surprised, because he had used it since he was a boy without knowing it was an intoxicant. A motion to advise the next committee to keep such advertisements from their minutes was made, but subsequently withdrawn. It would be in order for the enterprising firm to publish some certificates of the clerical gentlemen who have grown up on the drug.

Dr. Villemin, of Paris, the Vice-President of the Academy of Medicine, is said to be one of the leaders in the Buddhist propaganda which is just now amusing the fashionable world in Paris.

Honors to New York Physicians.—The Venezuelan papers announce that Drs. J. J. Henna and Robert F. Weir, of this city, have been decorated with the order of the "Busto del Libertador," in recognition of their services rendered to General Puga of that country. General Puga was suffering from a disease which necessitated the amputation of his tongue.

He Broke the Doctor's Jaw.—A physician of Brooklyn, one of the police surgeons, went recently to see a patrolman who was sick. The man was in bed when the surgeon called, but jumped out as soon as he saw him and struck him with his fist, fracturing his jaw and inflicting other injuries. The cause of the policeman's anger has not been made known.

A Leper at Boston.—Among the immigrants recently arriving at Boston was a Swedish woman whose appearance was such as to suggest leprosy. She was examined the first of this month at Quarantine, and was found to be without any doubt a leper. The woman was passed as all right by the English port physician at Liverpool, and by the steamship surgeon.

The Duty on Cod-liver Oil.—Many of the representative wholesale drug firms and manufacturing chemists of New York and Philadelphia have joined in a protest to Congress against the further imposition of a duty on cod-liver oil. They urge that cod-liver oil cannot be obtained in sufficient quantities in the United States, on account of the limited supply of fresh cod livers; that it is used not only as a medicine, but also as a food for weak persons, and that no other article can replace its excellent qualities for these purposes. They beg, therefore, that the Committee on Revision of the Tariff will place this medicinal article on the free list.

The Woman's Medical College, of Toronto, Ontario, was organized in 1883. A new college building has just been erected and was formally opened about two weeks ago.

The Massachusetts Homœopathic Hospital has appealed to the State for a grant of $120,000 to aid in the erection of several new buildings, and a bill for that purpose is now before the legislature.

A New Hospital in Portland.—The corner-stone of the Portland, Ore., Methodist Episcopal Hospital building, at Sunnyside, was laid recently with appropriate ceremonies. When completed the building will accommodate three hundred patients. The hospital will provide clinical material for the medical department of Willamette University.

Bellevue Hospital has improved its diet to the extent of making the average daily cost per capita forty-nine cents, instead of thirty-three as formerly, and even the patients notice the difference.

Death of the Elephant Man.—The *British Medical Journal* announces the death of John Merrick, who was well known in England as the "elephant man." This name was given him on account of a proboscis-like projection of his nose and lips, together with the peculiar shape of his deformed forehead. His disease was not elephantiasis, but a complication of congenital hypertrophy of some parts of the skeleton with pachydermatocele and papilloma of the skin. The deformity increased as he grew older, and the head became so large and heavy that when he lay down the head tended to fall back and produce a sense of suffocation. He was found dead in his bed in the London Hospital, and it was believed that the heavy skull had fallen backward while he slept and had dislocated his neck. Strangely, the hospital committee refused to have an autopsy made. The man had been exhibited several times before the London Pathological Society by Mr. Treves.

Invalids' Work.—Good health is not necessary to good work, says Dr. Whittaker, in the *Journal of the Medical College of Ohio.* Much of the best work in science, literature, and art has been done by invalids, he says, and illness should not be so universally invoked as an excuse for incapacity or an apology for indolence.

Refusing a Charitable Bequest.—Philip Maret, of New Haven, died several years ago, and, among other legacies, left $130,000, the interest of which was to go to the city of New Haven upon the death of his daughter, to care for the poor of the city. The daughter has died, and now it is said that the city government will refuse the bequest, alleging as its reason that the fund would simply be at the disposal of the ruling political party, as there were practically no provisions or conditions imposed in the legacy. The daughter, Mrs. Gifford, who died recently, left $300,000 with her lawyer, the income to be used as he thinks best for the lessening of the sufferings of all kinds of animals.

Dr. J. Dayton Munn, of Herkimer County, N. Y., died recently in Van Hornesville. He was a graduate of the Albany Medical College in 1844.

Physical Culture in France.—It is stated in the *Annals of Hygiene* that the Duchesse d'Uzes, of France, being greatly impressed by the physical development of English women, has returned to her native land fired with the ambition of making the French women equal to those of England. In accordance with this idea, she has started lawn-tennis clubs, and rowing clubs, and walking clubs, and is endeavoring in every way to make the French women interested in physical development.

The Electric Episcope.—At the German Congress of Internal Medicine, recently held in Vienna, Professor Stricker gave demonstrations with the electric episcope, invented by Herr Reiner, a Vienna medical student. This is an apparatus which makes it possible, by projecting objects moderately magnified on a gypsum plate, to show large objects, as, for instance, anatomical specimens of the cerebrum, etc., as well as experiments on animals carried out on a table, quite distinctly to an audience of four hundred persons. Professor Stricker showed the pulsating heart of a dog, and its changes under the influence of asphyxial blood. He also showed the human brain, and the movements of the intestines of a dog under irritation of the vagus. Professor Stricker also gave some interesting demonstrations with his electric microscope. He showed that by recent modifications of the instrument it was possible, by intense illumination, to attain even a magnifying power of 11,000 linear, and in this way to show, most distinctly, even bacteria to a large audience.

The Seventh Italian Surgical Congress was held at Florence, March 30th to April 2d; Professor Corradi presiding. Among the principal subjects discussed were: "The Latest Modifications in the Treatment of Wounds, with Special Reference to Drainage and to the Material Used for Ligatures;" "The Arrest of Hemorrhage in Resection of the Liver, and the Danger of Bile in the Peritoneal Cavity;" "Hypogastric Cystotomy;" "The Treatment of Abdominal Tumors;" "Resection of the Intestine;" "The Surgical Treatment of Tuberculosis," and "Various Modes of Treating Spontaneous Aneurism of the Internal Carotid." Professor Ruggi gave an account of the laparotomies performed by him since the last meeting—that is, in ten months. They amounted to 65, bringing up his total to 223. The cases included 5 of oöphorectomy with salpingectomy, all cured; 10 ovariotomies, all cured; 17 "castrations" for various reasons, with 16 cures and 1 death; 2 laparotomies for uterine fibromyoma and sarcoma, with 1 cure and 1 death; 9 supravaginal amputations of the uterus, with 7 cures and 2 deaths; 3 hysterectomies by Ruggi's own method, all cured; 2 for parametric cysts, both cured; 4 intra-abdominal replacements of the uterus, all cured; 3 for retroperitoneal and hepatic hydatid cysts, all cured; 3 exploratory operations, in all of which the patients recovered; and a few cases of a miscellaneous description (foreign bodies, tumor of pancreas, nephrectomy, etc.). Among the 65 cases there were only 5 deaths. Dr. Ferrari described a procedure for the radical cure of hernia, which he described as an improvement on Czerny's method; and Professor Postempski gave particulars of 41 cases in which he had operated by his own method, with 3 deaths. Dr. Postempski also related certain experiments on the cortico-motor centres of the human brain, which he had performed in some cases of head injury.—*British Medical Journal.*

A Salaried House Surgeon for Manhattan Hospital.—At the Manhattan General Hospital, Tenth Avenue and 131st Street, a House Surgeon is wanted (who must be a hospital graduate), to serve till November 1, 1890, at a salary of $50 per month. Apply in person, between 9 and 10 A.M., to Dr. F. H. Daniels, 126 West 126th Street, *Secretary of the Medical Board.*

Cerebro-spinal Meningitis is reported as prevailing to an alarming extent among horses in Kentucky.

The Connecticut State Medical Society will hold its annual meeting in New Haven, May 28, 29, and 30, 1890.

North Carolina Medical Society.—The thirty-seventh annual session will be held at Oxford, N. C., May 27, 28, and 29, 1890.

The Illinois State Medical Association.—The following officers were elected at the Annual Meeting of this Society, held on May 7, 8, and 9, 1890: *President*, Dr. J. P. Matthews, of Carlinville; *First Vice-President*, Dr. C. C. Hunt, of Dixon; *Second Vice-President*, Dr. F. C. Schaefer, of Chicago; *Permanent Secretary*, Dr. D. W. Graham, of Chicago; *Treasurer*, Dr. T. M. McIlvaine, of Peoria; *Assistant Secretary*, Dr. G. N. Kreider, of Springfield.

Cleveland's Colic.—The physicians in Cleveland are kept busy by an affection which seems to be epidemic, and which, for the want of a better name, they call "winter cholera." The chief symptoms are a severe colic, nausea, and a feeling of great depression. No deaths from the disease have been reported, but the patients, when attacked, feel that their last hour has come, and send in urgent haste for their medical advisers. The latter regard the disease, speaking financially, as almost equal to the influenza.

Examination for the Position of Eye, Ear, and Throat Surgeon to the Eastern Dispensary, New York City.—Applications are restricted to physicians who have had previous experience in hospital and dispensary practice and who are able to converse in German. Each candidate will be examined as to his practical familiarity with the diseases of the eye, ear, and throat, and with their treatment, and also as to his physical and general aptitude for the service. A daily service from 10 A.M. to 12 noon (Sundays and holidays excepted). Yearly salary, $400. Letters of application, which should be accompanied with such credentials, testimonials, etc., as may be proper, must be addressed to the chairman of the committee on applications of the Eastern Dispensary, 57 Essex Street, and will be received until May 28, 1890; after which date each applicant will be notified by letter of the time and place of examination.

The Sheppard Asylum.—Thirty-three years ago, Mr. Sheppard, of Baltimore, died, and left the sum of $560,000 for the purpose of building an insane asylum. Only the interest of the money could be used, however, and the institution has been slowly building ever since. It is now announced that it is nearly finished, and as a result of the delay, the trustees find that they have still a productive investment of $583,637.61, and buildings worth $881,262.27. The Sheppard Asylum will, therefore, when completed, be one of the richest institutions of the kind in the country.

The "Medicinesthe Revue" for Balneology, Hydro- and Mechano-therapy, Dietetics, and Hygiene, is the title of a new bi-monthly journal published in Vienna, and edited by Dr. A. Kállay of Carlsbad.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Fifth Annual Meeting, held at the Medical Museum and Library, Washington, May 13, 14, and 15, 1890.

DR. SAMUEL C. BUSEY, PRESIDENT, IN THE CHAIR.

FIRST DAY, TUESDAY, MAY 13TH.

THE Association was called to order at 10.15 A.M.

The President's Opening Address.—DR. BUSEY said his address would relate exclusively to some points bearing on the new constitution to be acted upon at this session. He approved of the new constitution, the chief points in which will follow. He referred with especial satisfaction to the discussion of scientific subjects by referees and co-referees.

Attendance on Congress of American Physicians and Surgeons, 1891.—In accordance with instructions of the Executive Committee of the Second Congress of American Physicians and Surgeons, Dr. Pepper (Chairman of the Executive Committee) appointed the following committee to represent the Congress in Berlin, so as to promote a full attendance of distinguished men from abroad at Washington, 1891: Drs. J. S. Billings, Harrison Allison, A. L. Loomis, R. H. Fitz, C. H. Mastin, William Osler, H. C. Wood, D. B. St. J. Roosa, A. Jacobi, H. P. Bowditch, H. N. Mastin, N. H. Shaffer, John Green, Forcheimer, J. N. Danforth, W. Pepper.

DR. JACOBI, Dhairman of the American Committee of the International Medical Congress, extended an earnest invitation to all the members of the Association to attend the Congress. He also explained that the committee was appointed by the German Executive Committee at an unfortunately late date in the formation of the Congress; and that this committee is composed almost entirely of physicians living in Eastern and Southern cities, because circular letters of invitation to join the committee sent to physicians in Chicago, St. Louis, and other Western cities were either not answered at all or were answered at too late a date.

The New Constitution.—The object of the Association was stated to be for the advancement of scientific medicine and practical medicine. The number of active members was limited to one hundred. The officers are, a President, Secretary, Recorder, Treasurer, elected annually; five Councillors to serve each one five years; and a Representative of the Executive Committee of the Congress.

The meetings shall be held annually at Washington. Papers are to be by voluntary contributors and by referees and co-referees. Annual dues are fifteen dollars.

Natural History of Typhoid Fever.—DR. J. E. REEVES, of Chattanooga, read the first scientific paper. It seemed that at no time of the world's history was the human race free from epidemic fever. Regarding typhoid fever, as of many other diseases, it could be said that an unstable nomenclature had led to confusion. He used the term typhoid out of deference to one who had early befriended him, Dr. George B. Wood. Probably the title enteric fever would finally prevail. The author gave a history of the disease as he had observed it for nearly forty years in country, town, and city. He quoted from a letter written him by Dr. Wood in 1859, giving excellent reasons for not confounding typhoid with typhus fever, which was common at that time. Typhoid was not a modification of typhus, and depended on a distinct cause.

Cause of Epidemics Unknown.—We could not tell why at times there were such wide-spread epidemics, and must be content at present to refer it to what had been termed by Sydenham and others as "the medical constitution of the air."

The author gave a partial history of the epidemic which prevailed in Virginia, which was attended by a frightful mortality.

Typhoid fever was defined to be an acute contagious febrile affection derived from an antecedent case of the disease, and depending for its communication from person to person upon the presence of a specific micro-organism of believed well-known morphological character; prevailing less commonly in tropical and subtropical countries than in the temperate zone; both endemic and epidemic in its visitations, attacking preferably young persons and those in middle life; of long duration, but varying from ten to forty days beyond, or in addition to, the prodromic period, which may cover from one to ten or twelve days; if not diarrhœa, relaxed bowels, and at all stages a marked susceptibility to the action of laxatives, with pea-soup or ochre colored stools; intestinal hemorrhage in many cases, and in fewer instances perforation of the bowels; epistaxis; tympanites, with gurgling on pressure over the ileo-cæcal valve; dulness of hearing; sometimes unusual acuity of hearing; mental hebetude or morbid vigilance; headache; delirium; rose-colored lenticular eruption; cough and bronchial râles; fever curve unlike that of any other acute febrile or inflammatory disorder; in fatal cases death during third or fourth week; constant and characteristic lesion of the small intestine, involving the solitary and agminated glands. He had nearly always noticed enlargement of the spleen; convalescence tedious; true relapses not infrequent; the disease affording as perfect immunity as small-pox from subsequent attacks.

Types.—The author spoke of three forms—the mild, intermediate, and malignant. Of one hundred and seventy consecutive cases which had come under his observation, sixty-four were mild. The majority had lasted between thirteen and eighteen days.

The Eruption.—He had seldom failed to find this, and while it was usually on the abdomen yet he had seen it from head to foot, and on various portions of the body in individual cases, not excluding the face.

Recovery after Intestinal Perforation.—He had seen five cases in which there was recovery after all the usual symptoms of intestinal perforation.

He believed there was some ground for the popular impression that pregnancy offered partial immunity.

Unusual Complications.—Among occasional complications he had noticed swelled leg. The disease occurred more frequently in autumn and winter, in males than females, whites than negroes. It was not endemic in Chattanooga, a city of sixty thousand inhabitants, and many unsanitary conditions.

DR. WILSON, of Philadelphia, said most text-books claimed the eruption never occurred upon the face, yet he had seen it in this locality in four young subjects.

Treatment by Cold Water.—DR. WILSON had practised Brandt's method of treatment by cold-water bath, keeping the temperature below 101° F., in thirty-seven cases, and must state that this treatment had had a remarkable effect upon the natural history of the disease. It changed the disease to a mild continuous febrile disorder which did not affect the intellect or nervous system in the usual manner, which was followed by a brief convalescence.

Types.—DR. A. L. LOOMIS, of New York, thought the terms mild and severe covered the varieties sufficiently without the use of the term intermediate.

Causes of Epidemics.—He thought we had to look for one or two causes of wide-spread epidemics of contagious diseases, namely, the condition of the soil or atmospheric causes, in addition to the elements which produced local cases.

Peritonitis was, as the author had stated, one of the most fearful of the accidents attending the disease, yet it might be recovered from, but he could not conceive of a case recovering after intestinal perforation and escape of the gases.

Œdema of the Feet was, he thought, not infrequent, and was, he believed, usually due to venous thrombosis attending cardiac weakness.

Softening of the Heart, a term which had been used by Hayden, was usually recovered from completely. But during its existence the patient was menaced by two dangerous accidents—cardiac thrombosis and dilatation. This disease, he thought, was a cause of many cases of cardiac dilatation. Hence the need of careful management during convalescence.

Subacute Gastritis, from improper feeding, was another accident which he had witnessed.

"**Typhoid Spine**" was a term applied by Dr. Gibney to a condition which Dr. Loomis had witnessed in one case in particular. The patient had previously been treated by different doctors for supposed sciatica, psoas abscess, and spondylitis. Dr. Gibney found only sensitiveness on pressure over certain vertebræ, enjoined rest, etc., and the symptoms entirely disappeared.

Dr. Weir Mitchell had seen mild spondylitis, with symptoms like those just described, follow typhoid, malarial, and other fevers. The treatment was similar—rest, etc.

Dr. A. Jacobi thought we should hesitate about introducing new names; for instance, "typhoid spine." The condition was probably a mild spondylitis, of which he had seen a good many cases.

Dr. Johnson referred to an endemic of cerebro-spinal meningitis preceded by the contamination of the waters above by large numbers of decayed potatoes, and followed by endemic typhoid fever.

Dr. Pepper had also collected a large number of typhoid cases in which there was periostitis and spondylitis, simulating diseases of the spine. He objected, too, to the introduction of a new name.

Uses Nitrate of Silver.—He spoke in the highest terms of nitrate of silver throughout typhoid fever.

Dr. Busey, in closing, expressed want of faith in cold baths. In private practice, too, they were impracticable.

Inflammations of the Appendix and Cæcum, and the Duty of the Physician Regarding Them.—A paper by Dr. Norman Bridge, of Chicago, bore this title.

1. The appendix vermiformis is, of all organs of the abdomen of males, most prone to dangerous inflammation. In females this tendency is exceeded by the pelvic organs alone. The appendix is fourfold more liable to inflammation in males than in females.

2. Primary inflammation of the cæcum is rare. The great majority of cases of so-called typhlitis and perityphlitis begin as appendicitis, the tissues of and about the cæcum being inflamed secondarily. Even where cæcitis occurs primarily, it is most exceptional for it to lead to ulceration and perforation. When the cæcum is perforated, it is almost invariably from without, and due to the pressure of an abscess, the result of appendicitis.

3. Probably failure of free evacuation of the appendix is the first step toward its inflammation. Filled with enteroliths, resulting from retention of its contents, and occasionally with foreign bodies, with mucus and products of decomposition, it becomes inflamed, then undergoes ulceration of the mucous lining, which may produce perforation, resulting in peritonitis or cellulitis, depending on the location of the opening; if peritonitis, a localized inflammation and probably an intraperitoneal abscess, or a general peritonitis and death; if cellulitis, perityphlitis with probably an extraperitoneal abscess.

4. Most cases in males of so-called "inflammation of the bowels," as characterized by many general practitioners, are instances of inflammation of the appendix or cæcum, with or without the involvement of the connective tissue about them, or the peritoneum, or both.

5. Most cases of peritonitis in male patients, and not a few in females, are due to perforation and infection from the inflammations named.

6. Many cases of supposed intestinal obstruction (intussusception and volvulus), with evidence sooner or later of inflammation, are simply instances of peritonitis from perforation of the appendix, or of abscess due to previous inflammation of the appendix and its results.

7. It is probable that abscess rarely occurs until after perforation, albeit inflammation of small surfaces of the peritoneum, often resulting in adhesions, does frequently happen without it.

8. The fatality of all cases of appendicitis is not great; the fatality of cases ending in perforation is great. The deaths are from peritonitis generally, occasionally from inflammation of the organs, from wasting discharges of the abscess, and from general infection through entrance of the products of the disease into the blood channels.

9. One-third of all post mortems, at least, show recoveries from previously existing appendicitis. The duty and aim of the doctor must be to determine clinically, if possible, the cases that form this vast class and commit them to medical treatment, while he insists on surgery for those that lead to death directly, or to the hazardous results of abscess. Can this determination be made with certainty?

10. The diagnosis of perityphlitis is usually easy. Localized pain, sometimes masked by complaints of pain elsewhere and by vomiting, more especially localized tenderness, soon some evidence of tumor over the cæcum (the appearances often being greatly exaggerated by tension of the abdominal muscles, which disappears under anæsthesia), possibly pain in the region on flexing the thigh, with some fever—all following possibly a sharp attack of diarrhœa, or vomiting, or both—are ordinarily sufficient. The diagnosis of appendicitis before peritiphlitis has occurred is more difficult, since there is no tumor; the tenderness is often slight and very deep in the abdomen. The diagnosis must be made largely by exclusion. Yet an acute appendicitis may be ushered in by vomiting and pain in the epigastrium, which may evoke such complaints as to mask the pain in the cæcal region.

11. A large proportion of first attacks, and probably many after attacks, of acute appendicitis will doubtless recover without abscess, and with only slight cellulitis or peritonitis and adhesions, under proper treatment, namely—quiescence in bed, hot applications, anodynes, light diet, and a rigid avoidance of all influences that can provoke intestinal peristalsis.

12. When to go beyond treatment of these diseases and resort to operation can probably not be determined by any absolute and fixed rule. Each case must be dealt with by itself to some degree, since cases differ widely, but there are certain general principles that ought to guide us, in view of which we cannot escape our full responsibility.

13. Reliance on treatment is justifiable, in acute appendicitis, in the absence of strong evidence of perforation, abscess, perityphlitis, peritonitis, or of any considerable induration lasting two or three days, or of protracted severe pain, or resulting high temperature. We can never know, however, when a catastrophe is to occur. A few cases falling in this category will suffer sudden perforation, general peritonitis, and death; but nearly all of them failing to recover promptly, will, if perforation occurs, have sharply localized peritonitis or perityphlitis, and probably abscess that will be readily diagnosed. That in over one-third of post-mortem examinations there should have been found evidence of previously existing appendicitis would seem to justify this rule.

14. Surgical interference is demanded:

a. In acute cases with rather protracted high temperature, and with distinct induration that does not yield in forty-eight hours.

b. In cases of undoubted severe inflammation lasting several days, even though no particular induration can be made out (violent appendicitis), and in acute localized peritonitis having its origin at the appendix and producing marked constitutional symptoms (threatened peritoneal abscess).

c. In all acute cases where large induration develops rapidly with high fever. Here extensive deposit and abscess are almost certain, and the operation should be early.

a. In all cases advanced to the subacute or chronic stage with distinct induration and dulness (regardless of the temperature), since in most such cases pus is present.

e. In all cases of undoubted chronic appendicitis with recurring exacerbations, even if no induration can be demonstrated. In all such cases the patient is in constant danger of perforation of the appendix and mortal peritonitis, and laparotomy and extirpation of the organ (if done antiseptically) reduce the hazard.

Dr. Atkinson thought that since so many cases of appendicitis recovered spontaneously the physician was justified in waiting, watching his case carefully, applying other than surgical treatment, until the symptoms plainly demanded the services of the surgeon before he invoked them.

Dr. R. H. Fitz based his views on a study of seventy-two cases, observed in Boston the past four years. Of the number seen seventy-four cent. recovered. Of cases treated surgically, forty per cent. died; treated medically, eleven per cent. died. There were explanations for the high mortality in the former. About one-half were in females. The lesion was not sufficient in many cases to cause the patient to seek relief. He would not operate simply because of recurrence, but frequency of recurrence would have an influence.

Dr. A. Jacobi did not doubt that recovery from appendicitis was frequent. First attacks did not kill, in fatal or severe cases evidences might be found of previous attacks. One should not operate in the acute condition, with high pulse, absence of tumor, etc., but wait, give opium, make local applications, and after three or four days a tumor would be discovered in which the operator would find pus. It never had struck him that puncture in these cases of tumor was dangerous.

Dr. Pepper thought that the time had not yet arrived for laying down fast rules governing the time of puncture or laparotomy. He believed much might be learned by rectal examination, especially in cases where the tumor, owing to its depth, could not easily be made out by external palpation. If the temperature continued high, the evidences of peritonitis marked, perforation being probable, although the mortality would be high no matter what was done, and although we were liable to err in diagnosis, yet the ordinary treatment was so uniformly attended by a fatal result that he thought the surgeon should be called in to share the responsibility.

Local Tuberculosis as Cause of Appendicitis had been observed in three cases by Dr. J. H. Musser. He agreed with the other gentlemen in not recommending an operation, except where the indications were clear.

Cast of the Bronchial Tubes.—The specimen, a very perfect cast of the bronchial tube and branches, was presented to the Army Medical Museum by Dr. W. H. Hawley, and had been obtained by Dr. Weist, Indiana, at autopsy on a woman, aged forty-eight, who had pseudomembranous bronchitis, during the course of which she had coughed up such specimens weekly. Later she developed pneumonia and died.

Varicose Aneurism of the Aorta and Superior Vena Cava.—By W. Pepper and J. P. Crozier Griffith. Dr. Pepper read the paper. A Chinaman, aged forty-eight; had had no previous illness. Except for the presence of small varicose veins on the thorax the symptoms began suddenly, and consisted in extreme dyspnœa and cyanosis of the entire upper portion of the body, with absolute orthopnœa. The lower part of the body was entirely unaffected. There was dulness on percussion under the right clavicle. There was also a rhythmic murmur of a distinctly venous quality, heard best at the aortic cartilage, loudest with the systole, fainter and lower pitched with the diastole. It was heard distinctly in the neck and under the clavicles, and even down the arms. On the day before his death the patient coughed up several ounces of bright red blood. The autopsy showed the presence of an aneurism of the ascending portion of the arch of the aorta, pressing upon the vena cava, œsophagus, and trachea. The vena cava was constricted throughout nearly its entire length, and communicated with the sac by an opening three-fourths of an inch in length. Short abstracts were given of twenty-eight similar cases found in medical literature.

The diagnosis, he said, was easy in some cases; perhaps impossible in others. Among the principal symptoms in diagnosis were cyanosis, œdema, and coldness of the upper part of the body, and other evidences of obstruction to the superior cava. These symptoms were present in greater or less degree in all the cases in which histories were given.

No lesion would produce them except one obstructing flow of blood in the superior cava. If the obstruction were situated below the entrance of the azygos the chest would share the œdema; if above, the chest would escape. The comparative suddenness of the varicose aneurism was an important sign. The chief feature of the murmur, which was present, was that it was continuous, for the reason that the passage of blood from the aorta into the cava through the opening was continuous.

Antisepsis in Midwifery.—Dr. W. T. Lusk, of New York, read the paper. In a former paper he had stated that the reported number of deaths from puerperal sepsis at the Health Department of New York City, between the years 1867 and 1875, was 1,947, or an annual average of 215.5. Population in 1870 was 942,292. Deaths from same cause, 1885 to 1889, 1,105, or an annual average of 221. Population in 1890, 1,755,292. Thus it would be seen that the death-rate from this cause had by no means kept pace with the city's increase of population. It would appear, then, that puerperal fever was a preventable disease. Among the poor in their own homes he thought the dangers from childbed had not been lessened. How serious was the question under discussion was shown by Dr. Maury's tables, taken from the statistics of the Board of Health of New York, by which it appeared that, even in the past five years, one-tenth of all deaths in women between fifteen and forty-five were due to causes connected with childbirth, and that one-twentieth of deaths among women in the childbearing period were due to puerperal sepsis. The author here referred to the condition which surrounded the Maternity Department of Bellevue Hospital, and the marked death-rate prior to five years ago. During the past five years 837 women had been confined (in the buildings on Blackwell's Island) under modern antiseptic methods, with 16 deaths, nearly 1 to 82. Five of the deaths were due to eclampsia, patients being in convulsion when received; 1 to placenta prævia; 1 to Cæsarean section; 1 to alcoholism. In others also there had been prolonged labor, or other serious conditions to explain the fatal result. In one, possibly two, there was puerperal sepsis.

The regulations by which these results had been obtained were comparatively simple. The patient on her entrance into the hospital received a full bath; a rectal injection was given; the lower abdomen, inner surfaces of the thighs, the pudenda and anus were scrubbed with soap and water, then washed with plain water, and finally cleansed with a 1 to 1,000 solution of corrosive sublimate. The vagina was douched with soap and water, and then with a 1 to 5,000 solution of corrosive sublimate. In operation cases these douches were repeated before and after introduction of the hand or instruments. The assistants were not allowed to attend autopsies, surgical operations, or erysipelatous cases.

Doctors and nurses were required to wash their hands and arms in soap and water, and dip them in corrosive sublimate solution. Instruments were boiled and placed in a solution of carbolic acid before use. The Credé method of placental expression was practised. When the uterus was invaded by the physician, it was afterward douched with the corrosive sublimate solution of 1 to 5,000.

The external parts were covered by Garrigues's pad of corrosive sublimate gauze, which was renewed at stated

periods, and the externals washed. The temperature rarely rose above 100.5° F.

The author said there was by no means unanimity regarding the necessity or advisability of some of these procedures, such as the vaginal douche, the antiseptic pad, etc.; but the class of patients admitted to the Maternity were from among the poorest, dirtiest, and those often previously handled by dirty midwives, and they certainly fared much better under this management than formerly.

Indications for Intra-uterine Douche. — Dr. Lusk thought this was indicated only where the case had been slovenly handled during childbirth, and usually one douche was sufficient. Its frequent repeated use was attended by relaxation of tissues and consequent dangers.

Dr. Welch, of Baltimore, said experiments by Dr. Halstead had confirmed the statement that the hands, etc., were not actually sterilized by ordinary solutions of corrosive sublimate, but the slight deposit of the agent remaining on the skin rendered the germs inactive. A favorable ground was necessary for pus bacteria to give rise to inflammation.

Dr. Jacobi was satisfied the number of deaths from puerperal sepsis in New York was greater than the statistics contained in the paper indicated—two hundred and fifty per annum.

Avoidance of Mischievous Measures, in Dr. Pepper's opinion, had tended to lessen the mortality from puerperal sepsis as well as had the adoption of excellent measures. He had been satisfied, by seeing cases of puerperal fever in consultation, that repeated douching was provocative of the condition.

Bichloride Solution Dangerous.—Dr. J. W. Roosevelt, of New York, had known poisoning to result from the use of solutions of bichloride, and said it was a question whether as good results could not be obtained from sterilized water.

Dr. Lusk said, that in a thousand or more cases in which he had known the corrosive solution, 1 to 5,000, to be used, no injury had resulted.

Seizures Characterized by Shock and Loss of Consciousness.—Dr. Israel T. Dana, of Portland, Me., in the first part of this paper mentioned briefly cases in which coma, with more or less of shock, occurred as an incident in the course of certain diseases which it could hardly be said to characterize. Thus we have the post-convulsive coma of epilepsy; the coma of certain fevers; at the onset of eruptive fevers, especially in children; cholæmic, diabetic, uræmic, anæmic, and dyspeptic coma. He said his main object was to collate and compare, chiefly as to clinical history, the four typical forms of apoplectiform seizure—the hemorrhagic, embolic, congestive, and uræmic.

The chief elements involved in such seizures were abruptness and violence of invasion, loss of consciousness, depression of vital powers, and, combined with these, other symptoms which gave character to the particular attack.

After giving the hemiplegic and other usual symptoms of apoplectiform seizures, the author referred to some curious aphasic phenomena. For instance, one man could pronounce only the word or sound "bondileck," and would suppose that in repeating this with various modulations of the voice, that he was composing poetry or talking intelligently. He superintended a store while in this aphasic state, the clerks, however, doing the talking. In another case, aphasia came on suddenly without hemiplegia or coma, continued complete for six weeks, and then disappeared as suddenly as it had come. Here he thought the cerebral lesion must have been slight.

The Congestive Form.—The pathological basis of this form, he said, was distention of the cerebral vessels with arterial blood, the actual state of the brain tissue being that of anæmia from pressure of the distended artery.

The Uræmic Form, he said, was brought about by toxæmia, or the circulation in the blood of urea or tissue waste, which should be thrown off with the urine.

Forms in which there was only a molecular change, not a gross lesion, had interested Dr. Lyman, and he cited two or three instances in which there was only slight disturbance of speech, which he thought must have belonged to this form.

Dr. A. L. Loomis said the differential diagnosis between cerebral apoplexy, embolism, and thrombosis, was very difficult in many cases. Some years ago he had made a series of autopsies in cases in which hemiplegia was a prominent symptom, preceded by more or less loss of consciousness, without aphasia, cases usually put down as those of cerebral apoplexy, but instead he found thrombosis with softening. Sudden hemiplegia preceded by coma, coming on before fifty, was due in most cases to extravasation. Coma coming on suddenly, attended by paralysis, after fifty, was more likely to be due to cerebral thrombosis with softening.

Is Uræmic Coma due to Toxæmia?—There were so many conditions in the brain in uræmia which might account for the coma, that he thought we could hardly say the cause of the coma was due to toxæmia in the large proportion of cases. A more frequent cause, he thought, was cerebral œdema.

Congestive Apoplexy?—Dr. Loomis could hardly conceive of this condition. The term, he thought, had better be dropped. If there was apoplexy, he thought there must be extravasation.

Localized Cerebral Œdema.—Dr. R. T. Edes said this condition had been suggested in cases of supposed cerebral hemorrhage or embolism in which autopsy had failed to reveal these. There were, of course, great difficulties in determining local cerebral œdema post-mortem. By analogy such a condition could exist. He thought the general mental condition sometimes remained clear and normal in aphasic cases, with only a tendency to become easily fatigued.

Dr. Jacobi had four times seen unilateral symptoms in uræmia in adults, caused probably by local cerebral anæmia which might have originated from reflex vascular contraction or œdema, and he asked whether any member had seen this condition in children.

Dr. Tyson could see no reason why uræmic coma might not be due to toxæmia. Analogous conditions were seen in chloroform and ether coma in which a gross anatomical or mechanical explanation had not been thought necessary.

Second Day, Wednesday, May 14th.

Discussion on the Disorders of Sleep.—Dr. S. Weir Mitchell opened the discussion with a paper treating of the physical, motor, and sensory disturbances of what he termed the pre-somnium and post-somnium. The author referred to the limited literature on the particular points of which he would treat. Reference was made to his first paper in 1876, again in 1878, his book, 1882.

First, the relation of psychical, motor, and sensory disturbances to the præ-somnium and post-somnium premonitory to insanity was briefly mentioned. Cases were cited in which these prodromes of insanity were connected with the eye, ear, and in one with olfaction.

There were epileptic cases in which the inhibition of the fits from any cause, including bromides, caused homicidal explosions.

Pre dormant Terror.—Cases were also cited in which there was persistent terror without delusion before sleep.

Sensory Disturbances.—Various feelings of præ-dormant numbness, affecting the legs, arms, etc., were noted; also motor disturbances, monoplegias, diplegia, hemiplegia. In disturbance of sensation, there might be brief migraine or paræsthesia, anæsthesia, affecting different parts.

In some cases he had observed "sleep ptosis." In his

note-book were half a dozen cases of pain in the leg on falling asleep, which disappeared only on motion. In some, morphine had to be resorted to to give sleep.

Shock in the Head.—Interesting cases were cited in which in sleep there was a sensation of sudden and violent shock in the head. The patient felt as if struck in the head. There might be flash of light, sudden sense of odor, etc. The intensity of the phenomenon, especially the first time, was alarming. In some it was preceded by a kind of aura or warning. In some there was presomnic jerkings, preventing sleep. In rare cases there were choreic symptoms only on waking in the morning.

Tonic Spasm.—He had seen two cases with marked pre-somnic tonic spasm of the lower extremities. Patients were otherwise healthy. Brief mention was also made of failures of respiration in sleep.

Insomnia.—Dr. C. H. Folsom, of Boston, co-referee in the discussion on disorders of sleep, limited his paper to insomnia. Like Dr. Mitchell, he had nothing to add regarding the physiology of sleep, and pathology of insomnia.

Causes of Insomnia.—Examination of his cases showed the following causes: 1. Perverse habits. 2. External causes, including sensations, habit, heat, cold, hunger, noise, etc. 3. Excessive intellectual or mental activity, including excitement, grief, fear, etc. 4. Reflexes, of which indigestion was far the most common. This might fail to be indicated in the usual ways; next genito-urinary reflexes. 5. Traumatic causes. 6. Auto-toxic, in acute diseases, rheumatism, malaria, nephritis, constipation, excessive use of tea, bromides, etc. 7. Exhaustion from wasting diseases, sexual excesses, impaired nutrition of the brain. 8. Insomnia of vascular origin, from hepatic, cardiac, and renal disease, cerebral hyperæmia, arterial sclerosis, in syphilis, during puberty, menopause, etc. 9. Vaso-motor causes. 10. The neuropathic temperament, usually inherited, sometimes acquired. 11. Other diseases, as hysteria, hypochondria, organic diseases of the brain, etc.

Treatment.—This ground was touched upon. It related to change of habit, hygienic conditions, change of place, use of drugs, but hypnotics required to be given with care, and with the fact in mind that their long-continued use might be injurious or dangerous.

Discussion.—Dr. Pepper thought something might be learned from a study of the phenomena of natural sleep, among the most striking of which was general relaxation and cutaneous insensibility.

Combat the Diathesis.—Dr. Lyman spoke of the importance of treating the special diathesis which was often the cause of the insomnia.

Dr. Peabody emphasized the necessity for looking to dyspeptic causes, which were sometimes obscured.

Dr. Sinkler referred to enlarged tonsils as a cause of insomnia in children.

Value of Hypnotism.—Dr. B. F. Westbrook had obtained good results in some cases of acute and subacute insomnia by hypnotic suggestion.

Sulphonal.—Dr. M. A. Starr found sulphonal a valuable hypnotic. It acted better when the stomach contained some food.

A Study of the Sensory Disturbances in Hysteria.—Dr. C. L. Dana said his object in presenting this paper was to report results of study of the anæsthesias of hysteria in thirteen cases, six males, seven females. The histories illustrated very well the four points in regard to hysteria which modern research had tended to bring out, viz.: 1, The comparative frequency of the disease in men; 2, the common characteristics of the disease, whether caused by shock, trauma, local irritations, or general depressing influences; 3, the presence of some of the objective symptoms or stigmata of the disease in all cases; 4, the combination of true hysteria with organic disease.

The points noted were the cutaneous sensation of touch, temperature, and pain, their disorders and distribution of them, the muscular and articular sensations, the vision, hearing, taste, smell, and reflexes. The most constant form of sensory anæsthesia was a limitation of the visual field; next, disorders of cutaneous sensations, pain sense oftenest, then temperature, last the tactile sense.

The muscular and articular sensibility were rarely involved, and hysterical ataxia was rare. The color sense was sometimes implicated, but the complete inversion of the formula was not seen. Color-blindness occurred in two cases. Limitation of the auditory field for high notes was common, and was usually associated with bone-deafness to some extent. Deafness to low notes was quite rare. The pharyngeal reflex was usually absent on the anæsthetic side in hemianæsthetic cases. Knee-jerk in hysterical hemiplegia was diminished or temporarily absent. In paraplegia it varied. Taste and smell were not lost except in the hemianæsthetic cases.

Dr. S. Weir Mitchell had seen a case of hysteria without motor disturbance but complete absence of pain sense except to strong heat.

Recent Observations on the Etiology and Treatment of Migraine.—Dr. Wharton Sinkler, of Philadelphia, in this paper, quoted observations of different writers on migraine connected with uterine disorders, eye-strain, nasal irritation, decayed teeth, etc. Also to unusual visual phenomena, and hallucinations attending attacks. The author had seen six cases in which the attacks had occurred on a certain day of the week. Among therapeutic measures used recently with success by various writers were antipyrine, phenacetine, eucalyptus, caffeine, and other remedies.

Leprosy Bacillus.—Cultures from a case detained at Boston quarantine were presented by Dr. H. C. Ernst.

Infectiousness of Milk from Tuberculous Cows.—Dr. Ernst also referred to a paper read by him at the association last year on this subject, and presented a rabbit and slides from a recent illustrative case. A physician in Lowell had a patient less than a year old who had never been fed upon anything but breast milk and one cow's milk. The health of the parents was good, the surroundings hygienic; the child, however, had symptoms of tubercular meningitis. He turned attention to the cow, which, however, seemed to a veterinarian healthy. In a week the child died of tubercular meningitis. Inoculation of healthy rabbits with milk from this cow developed tuberculosis of which they died, and the tubercle bacilli were found. Neither milk nor cow had yet been studied microscopically.

Culture Obtained from Vaccine Virus.—Dr. Ernst also gave results of recent investigations in cultures of vaccine virus by Dr. Martin, in the laboratory of which Dr. Ernst had charge. Cultures were made February 13th, from a vaccine vesicle. February 20th, a calf was inoculated—typical results. February 27th, another calf inoculated—typical results. February 25th, second generation from culture of February 15th, and March 5th third culture. Inoculations with these cultures gave typical results. The fifth generation gave a like typical result in calves. Two children had also been inoculated with success. One had been afterward inoculated with ordinary virus, but without success, showing the culture virus was identical in action with the ordinary, as it was in appearances. Dr. Martin, he said, would continue his investigations.

Considering the importance of this discovery, on motion of Dr. S. Weir Mitchell, a vote of thanks was extended Dr. Martin, and the hope expressed that he would continue his work.

Cultures of Tubercle Bacillus.—Dr. E. L. Trudeau presented a culture of tubercle bacilli in man and another of the bacilli in a guinea-pig, the latter having a crumpled appearance which to him was unique. It oftener produces tubercular pneumonia, while the other, as usual, produced diffuse tubercles.

Case of Unusually Slow Pulse.—Dr. Prentiss again presented the man whom he showed last year, of unusually slow pulse, the beats falling at times as low as eleven per

minute, and then often accompanied by fainting spells. To-day his pulse was twenty-five, the respirations thirty-two.

Purpura Hemorrhagica Rheumatica.—He also presented a boy, aged about ten years, who had pains and swellings about the joints, shifting, simulating rheumatism, accompanied with purpuric eruptions, hemorrhages from the bladder and bowels, and also into the true skin or between the epiderm and derm, causing sloughing. The patient also had attacks of violent pain in the abdomen and chest, and vomiting. The attacks came on at intervals of six weeks to three months.

Case of Acute Pancreatitis.—Dr. R. H. Fitz, of Boston, read the history of the case. The symptoms were those of acute obstructive jaundice, the obstruction having been found post-mortem to be due to a diffuse purulent infiltration of the pancreas. He contrasted this with the hemorrhagic and gangrenous varieties. There were only ten or eleven cases of pancreatitis on record.

A Case of Acute Diphtheritic Colitis with Peri-Pancreatic Fat-Necrosis was reported by Dr. William H. Welch. Patient, aged fifty-three, had been a hard drinker. Three days before death he became delirious, and was admitted to the hospital. Temperature elevated; when first observed, 101.5° F.; on day of death, 105.4° F. Pulse 120 to 132, compressible. Spleen not enlarged; abdomen tympanitic, tender on pressure, especially in epigastrium; urine slightly albuminous; tongue clean and moist; no diarrhœa, except a few hours before death he had an offensive liquid stool. Urine and fæces passed involuntarily. Patient became unconscious, and died two days after admission to hospital.

At the autopsy, which was made an hour after death, were found numerous foci of so-called fat-necroses in the transverse meso-colon, and in the adipose tissue around the pancreas, with beginning sequestration of the pancreas. Liver intensely fatty. Contents of bile-ducts and of gall-bladder viscid, clear, with only slight yellowish tint. Renal epithelium fatty. Ecchymoses, small ulcers, superficial necroses, and diphtheritic exudation in large intestine. The foci of fat necrosis, as well as the liver, bile, and spleen, contained in large number a single species of bacteria, which was isolated and studied in pure culture. The organisms were bacilli belonging to the group of colon bacilli, and probably identical with the bacterium coli commune. Cultures and microscopical specimens were exhibited.

He also reported a case in which symptoms suggesting intestinal obstruction existed. Exploratory laparotomy was performed. Numerous foci of fat-necrosis were found in the omentum and mesentery, and a swelling in the region of the pancreas, but no intestinal obstruction existed. Portions of the omentum containing necrotic foci were excised, and were examined microscopically by the writer. The abdomen was closed, and the patient recovered.

What Can and Should be Done to Limit the Prevalence of Tuberculosis in Man?—Dr. E. O. Shakespeare, of Philadelphia, in this paper expressed warmly the view that the exciting cause was the bacillus tuberculosis of Koch, that the disease was not hereditary; that it was infectious or contagious, and that inasmuch as this disease caused more deaths than any other, and present modes of treatment were very inefficient, it was the duty of the profession to proclaim these views, and take active steps toward its prevention. There should be destruction of the bacilli in excretions and secretions of the affected, and avoidance as much as possible association of the well with the sick. Rigid inspection of milk and meat was a necessity. There should be special hospitals for the tubercular.

Dr. Trudeau thought it better for the tubercular consumptive patient to be in a special hospital where he could be properly treated, and it was better also for the community at large in way of prophylaxis.

Dr. Johnson had found consumptive patients do better in the deserts of the West where the air was inimical to animal and vegetative life alike, and therefore to the tubercle bacillus, than at so-called health resorts where no measures were taken to destroy the sputa, etc., of the consumptives congregated there.

Dr. Ernst related some clinical instances which tended strongly to the view that the persons acquiring and dying of tuberculosis were infected by exposure in rooms where there had been other patients with tuberculosis. As he had been quoted erroneously he wished to state distinctly that all processes produced by the tubercle bacillus were tubercular, but by no means were all destructive processes of the lungs known as phthisis tubercular.

Dr. Bridge thought it would soon be regarded as malpractice not to search for the tubercle bacillus in all suspected cases.

Third Day, Thursday, May 15th.

Discussion on the Modern Methods of Examination in Diseases of the Stomach.—Dr. F. P. Kinnicutt, of New York, opened the discussion with a paper on the above subject (see p. 573).

Dr. F. C. Shattuck sent a paper in continuation of the discussion. The introduction of use of the Nélaton sound had brought about a new era in diagnosis of diseases of the stomach. There were two main divisions into which the physical diagnosis of diseases of the stomach naturally fell: 1, Secretion and its modifications; 2, the length of time required for digestion, propulsion and absorption, and the capacity of the organ.

The author here spoke of the different tests for the presence of hydrochloric acid. A number of tests had been given of which he gave preference to phloroglucin vanillin test, although he admitted not to have tried the benzo-purpurin test. He summed up his estimate of the diagnostic value of the sound as follows: 1, The sound renders it possible to determine accurately the length of time required for digestion; 2, it also enables us to determine with far greater certainty than was formerly possible whether the size and seat of the stomach have undergone any notable pathological alteration; 3, it is contributing toward the classification on a pathological basis of the conditions hitherto embraced under the vague clinical term dyspepsia; 4, chemical study of the gastric contents when persistently carried out is an aid in the diagnosis of some cases, but its value is still quite subordinate to that of the rational signs; 5, these methods are so time-consuming, and their results so uncertain that in their present form their application presents almost insuperable difficulties, except to the hospital physician, who must also have a larger staff of trained assistants than is usual in American hospitals.

Dr. George L. Peabody, of New York, had found the chemical tests of marked diagnostic value in some cases. He instanced that of a man in which some time ago he would not have hesitated to make a diagnosis of cancerous stricture of the pylorus. There was marked emaciation, and marked dilatation of the stomach and vomiting. They found, however, free hydrochloric acid constantly present in the vomited matter and contents of the stomach, and for that reason he now felt positive that the stenosis was of a non-cancerous nature. He had recommended an operation.

Dr. Forscheimer thought the methods entirely impractical for the general practitioner.

Dr. W. H. Welch complimented the author on his painstaking work, and said with regard to dilatation of the stomach that motor insufficiency had to be considered, and like in the heart the early stage could not be recognized post mortem.

Dr. J. West Roosevelt thought the fact that the general practitioner could not apply these tests clinically was no more to be considered than that he could not make detailed reports on pathological specimens.

Dr. Kinnicutt was satisfied that, with a little practice, following the instructions contained in his papers, anyone would find these tests easy.

Notes of Two Cases of Acromegaly.—Dr. J. E. Graham, of Toronto, Canada, before reporting these cases gave a brief historical outline of the subject. The disease was first well defined and named acromegaly in 1886. Up to July, 1889, eighteen cases had been collected by Maré, and six others of doubtful diagnosis. A detailed account was then given of two cases:

Case I.—Male, aged thirty-nine, presented the following marked features: Enlargement of the face; thickness of the lips, especially the lower one; face elliptical in shape, hypertrophy of superior and inferior maxillæ; atrophy of the optic nerves; enlargement and flatness of the hands, feet enlarged; arms and legs normal in size. The disease had been about five years in existence.

Case II.—Male, died, aged fifty-one. The disease commenced when he was about twenty-five years of age. He presented the following conditions: Enlargement of the head and face; eyebrows prominent; nose enlarged, superior and inferior maxillæ hypertrophied; lips thickened, especially the lower one; face elliptical in shape; chin enlarged in every way, resting upon the upper and anterior part of the chest; neck short and thick; marked kyphosis of lower cervical and upper dorsal regions; sternum very prominent; enlargement of the scapulæ, scoliosis, lumbar lordosis; hands enormously enlarged, as also were the feet. No marked change in the arms or legs except the knees, which were increased in size. No post-mortem examination.

In both cases soft parts and bones were enlarged. The vitality diminished; mental faculties retained. In diagnosis myxœdema and Paget's disease were excluded, as were also gigantism and local hypertrophies. The voice became lowered, there was sexual weakness, but children were born after commencement of the disease. He treated but one case, without apparent result.

Dr. M. A. Starr had seen the case referred to in the paper before it had come under the observation of Dr. O'Connell, the reporter. She came to the clinic because of roughened condition of the skin on the hands, later also of the face and other parts. It went on to a marked hypertrophy of the integument and soft parts. The thyroid atrophied. He showed the patient to the class as one of myxœdema, but later the bones also became enlarged, and he was convinced Dr. O'Connell's diagnosis of acromegaly was correct. This patient's voice also changed, and the intellect grew duller. There was paræsthesia. The case seemed to show a relation between the two diseases, acromegaly and myxœdema.

The following papers were read by title: "The Diathetic Causes of Renal Inadequacy," by Dr. J. N. Danforth; "Report of Cases of Angio-Neurotic Œdema," by Dr. S. B. Ward; "Etiology of Pleurisy, Especially in its Relation to Tuberculosis," by Dr. A. A. Smith; "Report of a Case of Dysentery and of Hepatic Abscess, in which Amœbæ were Present," by Dr. William Osler.

Officers were elected as follows: *President*—Dr. William Pepper; *Vice-President*—Dr. H. M. Lyman; *Treasurer*—Dr. W. W. Johnston; *Secretary*—Dr. Henry Hun; *Recorder*—Dr. I. Minis Hays. *Members Elected:* Drs. Hobart A. Hare and J. P. Crozier Griffiths, of Philadelphia; Drs. T. S. Latimer and H. M. Hurd, of Baltimore; Drs. S. A. Fisk and C. A. Dennison, of Denver; Dr. C. S. Bond, of Richmond, Ind.; Dr. R. L. MacDonnell, of Montreal, Canada. *For Honorary Membership:* Dr. Fordyce Barker, of New York.

To Keep out the Influenza.—The Postmaster-General of Australia was so fearful that influenza would get to Australia that he suggested that mails arriving from Europe should be fumigated. The Colonial Boards of Health rejected the proposition, as they thought such a measure would be useless.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, held in the Army Medical Museum, Washington, D. C., May 13, 14, and 15, 1890.

First Day, Tuesday, May 13th.

The Association was called to order by the President, Dr. D. W. Yandell, of Louisville, who read the annual address (see p. 582).

The Secretary, in his report, announced the deaths of Dr. David Prince, of Jacksonville, Ill.; Dr. T. H. Squire, Elmira, N. Y.; and Prof. Richard Volkmann, of Germany.

Surgical Treatment of Tumors of the Bladder.—Dr. P. S. Conner, of Cincinnati, read a paper on this subject. That the bladder may be the seat of morbid growths has been known from the earliest times, but only recently has the treatment of vesical neoplasm been other than medical and symptomatic, general or local, intended to relieve pain, arrest hemorrhage, and remove existing irritation or inflammation. Though occasionally an outgrowth has been discovered and removed in catheterization, yet surgical interference as a regular formulized method of treatment, at least in the case of the male patient, may be regarded as dating from 1874, the year in which were done the well-known operations of Billroth and Volkmann. A sufficient number of cases have now been operated upon to enable us to fairly well determine whether or not surgical interference is proper, what it can accomplish, and how best it is to be made. Surgical treatment is fully warranted if it relieves symptoms and promotes comfort, still more so if in any considerable proportion of cases complete cure follows the removal of a growth.

In the years 1874 to 1888, inclusive, not including fifteen cases operated upon by Sir Henry Thompson, but not reported in detail, 176 patients were operated upon, 124 males and 52 females, with an apparent resulting mortality of 22.7 per cent.; 26.6 per cent. among males, and 13.46 per cent. among females. Of the 40 deaths, 13 occurred after the lapse of thirty days, and these are not to be attributed to the operation itself. Not more than thirteen per cent. can be attributed to the surgical interference. In more than three-fourths of the cases relief has been afforded, either permanent or for many months, or years. In almost all the forty fatal cases there was for a considerable time complete freedom from pain and bleeding. Surgical treatment is not only justifiable, but demanded, in every case in which there is not either, on the one hand, great mildness of symptoms that have manifested themselves only occasionally and at long intervals, or, on the other, such extreme weakness as that any interference would only hasten the approaching end, or such extensive malignant disease of the bladder, or of bladder and adjacent parts, as to render it impossible to effect removal.

How best can the growth be reached? In women the shortness and dilatability of the urethra indicates this as the readiest way of reaching the tumor. Of the 52 cases operated on, in 43 the growths were reached through the dilated urethra. In the remaining 9 colpocystotomy or suprapubic section was done, the former in 4, the latter in 5.

In almost all the males the bladder has been opened, sixty times from above, and fifty-one times from below. The mortality of the two operations is practically the same. As a diagnostitial procedure the perineal operation is preferable; but a diagnosis can usually be made by careful consideration of the symptoms. In the majority of cases the bladder can be reached through the perineal incision, but in a certain number it is impossible to carry the finger much beyond the urethral opening. In these cases there must be some uncertainty in locating the growth and difficulty in effecting thorough removal.

By the high section, on the other hand, thorough digital exploration is possible, and if desirable the cavity can be illuminated. The operative procedure can be done with

more exactness. An existing prostatic overgrowth is no contra-indication, but the opposite. The removal of such hypertrophied mass may be at the same time effected. Aside from securing thorough drainage, every advantage seems to lie with the suprapubic operation. To operate aseptically and to treat aseptically is certainly easier with the suprapubic than the perineal method.

Unfortunately only in a small minority of patients is the growth situated in the upper segment of the bladder, the portion most easily reached and cut away. Will it ever be found practicable to dissect out the whole lower segment, taking away at the same time, of course, the upper, which can no longer be of any service?

What can be done with the ureters? Experiments on animals show that they may be turned into the rectum or urethra, or brought out through the skin, the latter having proved the safest and most satisfactory disposition.

In conclusion it may be said that:

1. Only after operation is there much chance for recovery from any kind of vesical tumor.

2. That an operation should be done in all except the least and most severe cases.

3. That, as a rule, in males, the bladder should be opened above the pubes.

4. That the removal should be made as complete as the situation and extent of the growth will permit.

Discussion.—Dr. Hunter McGuire, of Richmond: I do not believe that anyone who has opened the bladder for the removal of a tumor, by the perineal and by the suprapubic method, would hesitate to adopt the latter as the easiest way of getting into the bladder, and the most reasonable way to get the tumor out. I have done twenty-one suprapubic cystotomies and have lost one case, eight days after the operation, from surgical kidney. Most of the tumors for which operation is done are connected with the prostate gland. Frequently we find a small tumor which is obstructive in its nature, but which cannot be discovered by the rectal examination. Some of these can be removed. I have operated eight times for enlarged prostate, leaving a suprapubic fistula. All these patients have complete control over micturition and empty the bladder at will.

I have met with few tumors of the bladder except small papilloma, which I have scraped away with my finger.

Dr. A. Vanderveer, of Albany: I was much impressed with the paper of Dr. McGuire on the "Formation of an Artificial Urethra," which he presented three years ago. I had performed Harrison's operation through the perineum and can endorse what has been said in regard to the difficulty of reaching the bladder in some cases. About two years ago I operated for vesical tumor by the perineal route, and removed a large portion of a papillomatous growth. The disease, however, returned in six or eight months and I then operated by the suprapubic method some sixteen months ago. Since then there has been no return of the trouble. I was greatly impressed with the ease of the second operation as compared with the first.

In performing the suprapubic operation I have sometimes found that the procedure was facilitated by a slight transverse incision of the recti muscles.

Dr. John H. Packard, of Philadelphia: Some three years ago I read before this Association a paper on "Suprapubic Cystotomy for other Purposes than the Extraction of Calculi." I am much gratified to hear the testimony today in favor of that operation, but I cannot fail to recall the hesitation with which these views were then received by several of the Fellows. The dangers attributed to the suprapubic operation are wounding of peritoneum, infiltration of urine, and hemorrhage. The idea of troublesome hemorrhage may be entirely set aside. Infiltration of urine is avoided by proper siphonage. With care there is not much danger of wounding the peritoneum.

Dr. John Homans, of Boston: I wish to add my testimony in regard to the usefulness of the suprapubic operation. I recently operated by this method with perfect success. The operation on the bladder through the perineum requires a surgeon with an extremely long finger.

Dr. W. W. Keen, of Philadelphia: My personal experience with tumors of the bladder is limited to one case, in which I adopted the perineal route, greatly to my dissatisfaction. The case was one of papilloma in a young man. I had great difficulty, after entering the bladder, of telling which was tumor and which mucous membrane with the finger. In removing the growth I introduced the closed forceps until it lightly touched the bladder wall, and then withdrawing it one-fourth of an inch, separated the blades and caught the growth. I removed a considerable portion of the growth, which under the microscope appeared to be papilloma. The patient has not improved to any great degree, and I shall in a short time perform the suprapubic operation.

A year ago I operated by the suprapubic route for multiple stones, and had considerable difficulty in reaching the bladder until I had the patient's hips elevated by an assistant.

Dr. D. Hayes Agnew, of Philadelphia: The only remark which I have to make is in regard to the diagnosis. By introducing into the bladder an instrument like a miniature lithotribe, it is possible to remove a portion of the growth and submit it to microscopical examination. In several instances I have made the diagnosis in this way.

Dr. Charles T. Parkes, of Chicago: My testimony is in favor of the suprapubic operation. I agree with the author in regard to non-interference in the mild and very late cases. I have operated three times by the suprapubic method for the relief of tumor. One case was papilloma in a child three years of age. The operation gave complete relief. A second case was that of a man, forty-five years of age, with symptoms indicating papilloma. The bladder was opened and a large mass of papilloma, occupying the lateral surface and somewhat of the base, was removed. This man was relieved of his suffering, but died two weeks after the operation from pneumonia. In the third case there was enlargement of the middle portion of the prostate. A large part of this was torn away with forceps. The man did well for a few days, and then some complication occurring, I made a perineal section to secure drainage and the man recovered.

Dr. L. McLane Tiffany, of Baltimore: In cases of prostatic growth I believe in suprapubic cystotomy and the removal of so much of the growth as interferes with the free discharge of the urine. I have drained a number of cases of enlarged prostate through the perineum, and while the patients have improved for a time the ultimate results have not been satisfactory.

The tumors of the bladder itself may be divided into the malignant and non-malignant. Of the latter, papilloma is the most common. In these cases the suprapubic operation is the preferable one. In malignant tumors of the bladder the treatment is only palliative. In one case of malignant disease at the base of the bladder I opened the organ through the perineum and had great difficulty in reaching the growth with my finger. In this case I simply drained through the perineum and the man lived in comfort for six months.

In many of these cases of tumor of the bladder the question of surgical kidney arises. Where there is reason to believe that such a condition exists on one side, it might be wise to pay attention to this, at the time of operation, by section and drainage or in other ways.

Dr. H. H. Mudd, of St. Louis: I have found the operation from above very satisfactory in the removal of tumors, and, in some cases, of stone in the bladder. In two cases, one in my own practice and one in that of another operator, the peritoneum has been opened; the openings were at once closed, and no bad results followed.

Dr. John E. Owens, of Chicago: I think that in these

cases there is danger of opening the peritoneum. In one case on which I operated, although both the rectum and the bladder were distended, the fold of peritoneum was only three-fourths of an inch above the symphysis. In doing this operation we should proceed with as much caution as though we expected to find the peritoneum at the lowest possible limit.

Dr. S. H. Weeks, of Portland, Me.: It seems to me that little can be done in malignant tumors of the bladder on account of the difficulty of the early diagnosis, the sessile condition of the growth, and the liability of the adjacent parts to be involved. I have no doubt that in pure papilloma, suprapubic cystotomy is the operation. The question has occurred to me whether or not, in enlarged prostate with inability to pass any urine, suprapubic cystotomy, with the view of removing the growth, was the best operation. Would it not, in such cases, be better to make the operation described by Dr. McGuire? I have two patients who have been unable to pass any water voluntarily, one for five years and the other for two years, yet they get along very comfortably by the use of a soft catheter.

Dr. P. S. Conner, of Cincinnati: In preparing this paper I purposely excluded all tumors which were not strictly tumors of the bladder. I had nothing to say about tumors of the prostate. The great majority of the deaths were not from the operation, but from the condition calling for operation. The mortality of the high and the low operation is practically the same. There is no question of the great advantage offered by the suprapubic operation.

It has been suggested that there is no use in operating on malignant cases. Although in these cases the operations have been done at an advanced stage of the disease when cure could not be expected, yet the patients have been afforded a relief from suffering and hemorrhage in many of the cases. If the time ever comes when we can remove the lower portion of the bladder, where malignant tumors are usually located, we may then hope for permanent relief in many cases. For it is remarkable how long the disease may remain confined to the walls of the bladder without extension to the glands or adjacent structures.

The Treatment of Fractures of the Shaft of the Femur.—Dr. Stephen Smith, of New York, read a paper with the above title. He said:

This subject has been assigned to me by the Committee of Arrangement. While I should hardly have selected a subject about which there is so little contention, yet it is nevertheless true that it is one of abiding interest with the general practitioner. With him the pressing question is what method of treatment shall be adopted which, while it will insure average good results, is within his ability to apply and is within his means. It would doubtless be a valuable service to the profession at large should this Association formulate a method of treating fractures which every practitioner could easily and safely apply, and which would give results which on the average were as favorable as those of any other method. I shall perhaps best fulfil the purposes of the committee if I limit this paper to a presentation of my own views of the indications of treatment in the several forms of fracture of the shaft of the femur, and the best manner of meeting these indications by a simple method adapted to the resources of the general practitioner.

The fractures which will be considered are: 1, Fractures below the small trochanter—sub-trochanteric; 2, fractures in the middle portion of the shaft; and 3, fractures at the base of the condyles—supracondyloid. It is proposed also to limit the variety of fractures to the ordinary simple oblique fractures without complication; the indications for treatment as learned from a study of the normal configuration of the bone, the peculiarities of the displacements, and the forces which maintain displacement, were then considered.

The treatment of fractures at the three points indicated should consist in extension in a straight-line position and the adjustment of suitable coaptating appliances to the limb at the seat of fracture. Of the methods of making extension, none can compare in efficiency and comfort to the patient with rubber plaster to the leg and the weight attached to the stirrup at the foot, with counter-extension by elevating the foot of the bed. Of the coaptating appliances none exceeds the plaster-of-Paris dressing. If applied as here proposed, five or six days after the fracture, no damage will be inflicted.

The first requisite is a suitable bed with a firm surface, with an opening for the passage of the evacuations. The foot of the bed is elevated four to six inches.

Extension should at once be commenced. The preferable extending apparatus is the rubber plaster and weight. When the rubber causes irritation, it may be replaced by a plaster-of Paris dressing to the foot and ankle, around which a cord may be fastened for the attachment of the weight. The weight should be sufficient to extend the muscles to the desired length, so as to bring the ends of the bone in apposition. A good general rule is to apply as many pounds as the patient is years old, up to twenty, but the effect sought is the better guide.

Four coaptating splints should next be applied to the whole length of the thigh and firmly compressed by four stout tapes. These splints should be of light wood and of such width as to nearly touch each other. This treatment should be continued for five or six days, at which time the limb should be in condition for the application of a permanent dressing.

No change is to be made in the extension, but the splints are to be substituted by a plaster-of-Paris dressing in each form of fracture. A roller bandage of heavy blanketing is first passed around the thigh, commencing just above the knee and extending as high as the waist-line. The plaster bandage is then applied until three layers are added. When the bandage reaches the fractured bone, a mass of cotton wadding is applied to the lower end of the upper fragment, and an assistant presses the bone firmly in contact with the lower fragment, and maintains this pressure until the entire bandage is applied. If, when the bandage has hardened, it is too tight at any point, it may be cut sufficiently to relieve the pressure. This bandage should be continued in position at least six weeks, and if in good condition it may be retained eight weeks. At the end of four weeks the extension may be discontinued and the patient may move about on crutches. If the splint becomes loose, it should be cut along the outer and posterior part and then tightened with three or four straps with buckles.

If the fracture is in the middle part of the thigh, the plaster bandage should be applied from three inches below the knee to the groin. If the fracture is at the base of the condyles, the bandage should extend from the middle of the leg the entire length of the thigh. It is important in fracture at this point that the foot should be kept in a position of extension on the leg during the entire course of treatment, in order to secure as completely as possible relaxation of the muscles of the calf.

If the practitioner prefers the use of splints to the plaster of Paris, the four splints first used may be continued, but in this case the long side-splint should also be employed.

I am aware that I have advanced nothing novel. The same general ideas have been presented to the profession in the writings of Professor Hamilton. As a pupil, I traversed this ground with him and saw every possible test applied, and as a result came to fully endorse his conclusions. He did not claim that treatment of fractures of the femur in the straight position secured perfect results. On the contrary, he established the fact that perfect results could not be obtained uniformly in oblique fractures by any method of treatment yet devised. His mature conclusion was that, as a rule and in the hands of the general practitioner, the straight position gave, on the

average, the best results. And this conclusion is enforced by my own experience.

Discussion.—Dr. D. Hayes Agnew, of Philadelphia: Fracture of the shaft of the thigh occurs most commonly at the junction of the middle and lower third of the femur. In fractures at the upper third the upper fragment is displaced by the iliacus and psoas muscles and becomes the troublesome fragment in the treatment. There are only two methods of treating fracture of the femur, that is in the angular position and in the horizontal position. For every fracture of the femur, with the exception of that at the upper third, I agree with Dr. Smith in recommending the horizontal position. In fractures at the upper third I think that the double-inclined plane with extension in the line of the femur answers best.

In regard to the mattress, the opening in it is usually too large. It should not be more than three inches or three and a half inches in diameter, as it increases in size. This opening is unnecessary. With a little skill a bed-pan can be introduced from the sound side, or the evacuations can be received on a wad of oakum.

Extension is in my judgment best accomplished by adhesive strips extending from the upper end of the lower fragment to three inches below the foot, and ending in a stirrup. It is unnecessary to restore the fragments to their proper position at once. For the first two or three hours, it is best to make no attempt at extension. At first eight or ten pounds is sufficient, and this will gradually pull down the lower fragment. If the lower fragment comes down in six or eight days it is all that is required. The weight may possibly have to be increased to twelve or fifteen pounds, but I have not seen more than this needed.

Lateral support is imperative, and I think that this is best afforded by the use of sand-bags, a longer one on the outside and a shorter one on the inside.

There is another displacement, and that is a little external rotation of the foot. This is readily overcome by a piece of bandage tied around the foot and secured to the inner sand-bag.

I take exception to one point referred to by the author, and that is in regard to the application of the plaster bandage. We cannot apply such a dressing without to some extent disturbing the seat of fracture. If the plaster bandage is applied accurately, there will follow a certain degree of atrophy of the soft parts, and the limb will lie in a sort of inflexible shell. After union has taken place, I see no objection to a slight support to the limb to prevent accidents when the patient first begins to go about.

There is one point which was not brought out in the paper, and that is whether in the adult we are to expect cure without appreciable shortening. For myself, I do not believe that it is possible by any contrivance to cure a fracture of the femur without appreciable shortening.

Dr. John H. Packard, of Philadelphia: In regard to what may be said to be a satisfactory result in fracture of the femur, I should say that the fracture is satisfactorily cured when the patient is able to walk without perceptible limp, and with his usual strength. I do not believe that it is possible to cure the fracture without a certain amount of shortening.

In fractures of the middle of the calf, we must remember that we have behind a mass of muscles which can be relied upon to keep the fragments in place, if supported by a splint to the front of the limb, of tin or binder's board. This obviates any tendency to bowing backward, the worst deformity that can follow. I agree with Dr. Agnew that the weight needed does not as a rule, exceed ten or fifteen pounds. I think that the plaster bandage is objectionable for several reasons. It cannot be readily removed to admit sponging and bathing of the limb, which is important in the later stages of the treatment. I much prefer a long zinc splint fitting the outer side of the limb, and held in place with a bandage. This can be readily removed when necessary.

Dr. John A. Comingor, of Indianpolis: In the West we depend largely on the plaster bandage in the treatment of fractures of the thigh. We have used that for many years. We apply the bandage at once. This facilitates the absorption of exuded blood and prevents consequent swelling. Many of us think that the plaster bandage affords all the extension that is needed. If the parts are placed in apposition, and the muscles stretched when the bandage is applied, we get certain bearings that keep up the extension. The bandage is left ten days, and then if necessary it is removed, and if everything is right reapplied for another ten days. In this way the inspection can be made without disturbance of the parts. With this dressing it is not necessary to confine the patient to bed any length of time. In the course of a couple of weeks the patient can go on crutches. It seems to me that we obtain better results with the plaster bandage than with any other method of treatment.

Dr. J. R. Weist, of Richmond, Ind.: I think it important to make a distinction between the treatment of fracture of the femur in adults and the same injury in children. I have here a table of forty-one cases treated in private practice, and of this number nine were children under five years of age. At this age I do not think that Buck's extension is required. Where the fracture is above the middle, I have used plaster-of-Paris splint, including the thigh and pelvis. Where the fracture is at or below the middle, I have used coaptation splints. These have proved sufficient. My experience leads me to believe that there is a decided difference in the management of cases between five and twenty years, and those at a later period of life. I had expected to hear some statement as to what are average results. I consider that I have obtained a good result when the shortening has not exceeded one-fourth of an inch. I do not employ the plaster-of-Paris dressing in the treatment of fractures of the shaft of the femur, except in fractures above the middle of the thigh in children under five years of age. I feel better satisfied with a dressing which I can remove and inspect the limb at pleasure.

Dr. H. H. Mudd, of St. Louis: It seems to me that we get the best results with moderate extension. In St. Louis we almost entirely use Hodgkin's splint, which is easily applied and can be made by any blacksmith. In the majority of cases of fractures of the shaft of the femur, it will give results which are practically perfect. Many years ago I abandoned the treatment of fractured thigh by the plaster bandage. Hodgkin's suspension splint permits any adjustments to be made without disturbing the fracture. The patient can move at pleasure or sit up if he desires.

The President: For twenty years I have not used anything in the treatment of fractures of the thigh but the plaster-of-Paris dressing. I do not employ the extension apparatus. Writing on this subject in 1870, I said that the time for the application of the fracture dressing was at the moment of the accident; the place, where the individual was; the way, the plaster-of-Paris bandage. I do not claim better results than others, but I secure a great deal of convenience to the patient.

Dr. S. H. Weeks, of Portland: An important indication in the treatment of fracture of the shaft of the femur is fixation of the joint above and below the fracture. This has not been dwelt upon to-day. This indication is probably best fulfilled by the long Liston splint. In fractures of the upper part of the femur where there is a tendency for the upper fragment to become displaced, I have applied a bag of shot or sand to keep it in place.

Dr. Stephen Smith: In my paper I confined myself to the treatment of simple fractures in adults. I purposely excluded fractures in children. In regard to Hodgkin's splint, I may state that it was tried by Professor Hamilton in a series of cases, and he states that his worst results were obtained with that splint. I had intended to suggest that a committee might be appointed to formulate some conclusions, first as to the results to be expected in fractures of the shaft of the femur, and

second as to the methods of treatment; but in view of the apparent diversity of opinion on these matters, this seems impossible.

A Rare Form of Epithelioma of the Hand, by Drs. Charles B. Nancrede and Heneage Gibbes, of Ann Arbor.—We shall first refer to the pathological changes and then to the clinical history. While the pathological appearances of this growth suggest the presence of arsenic, a disease similar to if not identical with that termed arsenic keratosis and cancer by Mr. Jonathan Hutchinson, and considered by him to be due to the internal use of arsenic, the clinical history shows that arsenic was not the cause in this case.

Sections of the growth stained with logwood show two kinds of changes, irregular masses which have a yellow color and columns of epithelial cells which permeate the sections giving the appearance of a net-work of trabecula. Filling up the interstices between these is a connective tissue showing evidences of rapid formation. The yellow masses are composed of cells undergoing a horny change. The epithelial trabecula are composed of cells similar to those found in rapidly growing epithelial cancer of the squamous variety when infiltration of the deeper tissue is going on.

The important point is the relation between the horny growths and the rapidly growing epithelioma. It seems evident that the former has been slowly formed. It would seem that the morbid growth was at first a simple keratosis, which by prolonged irritation set up an epitheliomatous growth, but it is difficult to see how this irritation should become at once universal throughout the growth. The epithelioma is growing rapidly and the small size of the trabeculæ show that it cannot have existed for a long time.

The patient was a widow, aged sixty-seven, who had been pecked by a hen on the dorsum of the left hand twenty years ago. The wound left an ulcerated surface which after repeatedly scabbing over, apparently healed six or seven years ago, when from its former site, a dry brown warty growth started having a base of perhaps one-third of an inch. This was removed by a ligature, but a series of warts replaced the primary one. Pain has been a prominent feature for the past five years. Eighteen months ago, muriatic acid was applied to the surface, which was then three fourths of an inch in diameter. After this the sore rapidly increased in size. The patient then consulted a physician, who for a short time applied arsenic locally as a caustic. The ulcer not improving, we were sent for, and amputated through the middle of the forearm, December 27, 1889. The patient rapidly recovered. So far there has been no local or glandular involvement. We have been informed that on the other hand a keratoid-looking mass has appeared, but of this we have no personal knowledge.

We cannot but consider that our case throws some doubt upon the deductions of Mr. Hutchinson as to the specific causative relation existing between the prolonged internal use of arsenic and the keratoid and the epitheliomatous changes in the diseased areas. In view of the commencing keratoid changes, on the other hand, the case will be kept under observation and reported upon at some future time.

Second Day, Wednesday, May 14th—Morning Session.

The Pathology and Treatment of Club-foot, especially Varus and Equino-varus, with Brief Clinical Reports of Fifteen Excisions of the Astragalus for the Correction of this Deformity.—This paper was read by Dr. Thomas G. Morton, of Philadelphia.

Club-foot is not a product of modern civilization. It existed as far back as our records extend, and it presented the same problems to the early physicians that it does to the surgeon of to-day. It is only our ideas of its pathology and methods of treatment that have changed.

The history of the operative treatment of club-foot naturally divides itself into three periods. In ancient times such poor results followed cutting operations that they were practically abandoned, and manipulations and bandages relied upon. This sufficed in the simpler cases, as it does to-day, but the graver forms of the malady were regarded as hopeless malformations. The second period began about 1834, when Stromeyer first published an account of his method of tenotomy. The third and present period began with the introduction of the antiseptic wound treatment, first scientifically formulated by Sir Joseph Lister, less than a score of years ago. With thorough antisepsis inflammation and suppuration may be said to no longer exist.

Pathology and Morbid Anatomy.—The pathology of congenital club-foot is in some points perhaps still unsettled. In the acquired, non-traumatic form, it is generally admitted that the larger proportion of cases have their origin in infantile paralysis. As regards congenital club-foot, there are good reasons for believing that in some cases, if not in all, the affection in its pathology resembles very closely the infantile form of spinal paralysis, if indeed it be not identical with it. In any given case of club-foot, we shall find in one or more of the muscles or groups of muscles of the leg and foot more or less paresis or actual paralysis, and in other opposing or correlated muscles, tonic spasm or contraction.

In explanation of the differences between various grades of congenital club-foot, it seems reasonable to assume that the amount of deformity is dependent upon the period of intra-uterine life during which the nerve lesion or palsy occurred. At an early period of fœtal development it is apt to give rise to the more marked forms of tarsal distortion. Later on there is less likelihood of malformation and displacement of the bones, the distortion being mainly in the soft structures. Later in life we see an inveterate form of varus or equinovarus, due either to ineffectual or improper treatment or to neglect of after-treatment, or to entire want of treatment.

The important features in the pathology of club-foot are:

1. The period of life at which it occurred.
2. Whether or not the foot had been used in walking.
3. Whether or not there had been any previous treatment or unsuccessful operations.

At birth there is one form of club-foot of such constant occurrence that it may be regarded as the typical congenital variety; it is varus or equino-varus.

The modern treatment of talipes is the direct result of our present methods of wound-treatment. It would have been impossible without the aid of antisepsis to perform the operations now practised, or to have improved so generally upon the old methods of treating these deformities. There is still great diversity of opinion in regard to the treatment of talipes, and even in the more inveterate forms of deformity in young persons and adults the operation as yet has not been established. There can be no routine treatment of these conditions; each case must be studied by itself, the object being to restore the deformed foot to as near the normal condition as possible, to retain it in this position, and to restore its functions as soon as possible. Excluding all forms of foot deformity which include valgus and calcaneus, and which give rise to little if any difficulty in their treatment, the discussion will be confined to the two really important varieties of congenital club-foot, varus and equino-varus. These may be considered under two heads: 1, The simple or uncomplicated; and 2, the complicated.

1. **The Simple or Uncomplicated.**—In these cases there is little or no change in the articulation of the bones of the tarsus, and they can usually be relieved by simple measures. If, when the child is ready to walk, equinus exists even to a moderate extent, the tendo-Achilles should be divided, but the tenotomy should not be performed until this time. Appropriate light apparatus should be worn from an early age.

2. **The Complicated Form.**—In these cases, while the varus can usually be overcome without operation, the equinus cannot be so overcome, and the foot cannot be brought to a right-angle position with the leg. It will be found in such cases that the normal depression on the dorsum of the foot, just in front of the fibula especially, is filled with a prominent mass of irregular bone, which can be readily outlined, especially if the foot is placed in a position of extreme varus. This is the astragalus forced out of its normal position of articulation with the os calcis, as a result of long-continued tendo Achillis contraction exerted probably from an early period of life —fœtal life—partial or complete dislocation backward of the tibia and fibula has occurred while the astragalus is at the same time pushed forward and from its natural position and rotated. The leg-bones then rest upon the calcis and a new joint is formed, while the displaced astragalus represents a sort of wedge in front of the ankle-joint, interfering with joint motion and preventing flexion of the foot at a right angle. It is to this pathological condition that our attention must be chiefly directed in treatment. A large number of the failures of operation in talipes have probably been due to a failure to recognize this condition. I am inclined to believe that, if this view of the case is correct, tarsotomy, tarsectomy, and the open incision will rarely if ever be required in the treatment of the congenital form of equino-varus described. I have operated on such cases by tarsectomy and open incision, and have later been compelled to remove the astragalus in order to bring the foot properly to the ground. The bones removed have been so altered in shape as to be unrecognizable as the astragalus. The removal of the astragalus in these cases in no wise shortens the limb, because the tibia and fibula do not articulate with this bone but with the os calcis.

We may now consider those cases of aggravated or inveterate deformity, whether congenital or acquired, and which have resulted from improper treatment or neglect of treatment, and which may be called inveterate club-foot. Congenital or acquired varus or equino-varus readily become aggravated by walking, partly by the action of the muscles, but principally by the weight of the body. The deformity may go on increasing until the patient walks on the cuboid, or even upon the dorsum of the foot. Whether the deformity is congenital or acquired the object should be to effectually rectify the malposition, so that no disposition to contraction can be observed at the time of the operation. I should lay down the rule that all interfering soft structures, soft parts, or bones should be sectioned or excised. It will be commonly found in the congenital forms that the astragalus is the obstruction to rectification. When tarsectomy is practised, it must first be demonstrated that the astragalus is not the cause of the distortion. If the astragalus be the source of deformity, it will be found if it be removed that the foot will unfold and be brought into a good position by moderate manual force. Occasionally there will be found great fore-shortening of the skin and deep soft tissues on the inner side of the foot, and it may be necessary to divide these tissues freely. In order to obviate the contraction which would necessarily follow such an open wound, which must also be of considerable size, I have made a plastic operation by turning upon the wound a flap of integument from the dorsum of the foot.

The treatment of talipes varus and equino-varus, congenital or acquired, simple, complicated, or inveterate, may be briefly summed up as follows: 1. Simple or uncomplicated congenital varus and equino-varus can be cured without operation, other than occasional section of the tendo Achillis. 2. Complicated congenital equino-varus which is associated with dislocation or displacement forward of the astragalus, requires excision of this bone and tenotomy of the tendo Achillis. 3. Mild, severe, or inveterate talipes, whether congenital or acquired, which has never been treated, or which has been neglected after treatment, or improperly operated upon, may require, according to the deformity, tenotomy, excision of the astragalus or cuboid, tarsectomy or open excision, or a combination of these operations, according to circumstances.

The operation for excision of the astragalus presents no special difficulty. An Esmarch bandage should be used. The astragalus is subcutaneous, and readily exposed by a curved incision including the most prominent part of the bone, and extending from the end of the external malleolus, in a straight or slightly curved line, to the base of the metatarsal bone of the middle ring toe. The attachments of the bone are then separated, and it may be lifted with bone-forceps. The tendo Achillis should always be divided. The edges of the incision are brought together with interrupted gut sutures, and a few strands of the same are carried to the bottom of the wound to insure drainage. Immediately after the operation, the foot should be capable of being placed in an easy natural position without any tension. If there is the slightest tendency for the foot to assume an abnormal position, search should be made for the contracted tissues and such should be sectioned. Before, during, and after the operation, rigid antiseptic measures should be employed. A well-padded posterior right angle tin splint is applied, care being taken to have the heel well down and the deformity slightly over-corrected. If there is no soiling of the dressing, it need not be changed for several weeks. At the end of a month, usually, the wound is firmly closed, and shortly after this, or as soon as the child makes any effort, he should be encouraged to walk, when the splint must make way for the ordinary talipes walking shoe. After considerable experience, I am prepared to believe that tarsectomy and open incision, except in the inveterate deformities in those of more mature years, or in adults, will seldom, if ever, be required.

The clinical notes and photograghs of ten cases were then given, in which the treatment by excision of the astragalus had given results that could be attained by no other method with which the author was acquainted. The following *résumé* of these cases was given:

The records of these cases present fifteen excisions of the astragalus for congenital equino-varus upon ten patients. With one exception all were males. Five had been unsuccessfully treated in infancy or early life by tenotomy, tarsectomy, or otherwise. In four cases both feet were operated upon at the same time. Four of the patients were under two years of age. The others were respectively aged, three, four, six, seven, fourteen, and sixteen years. The line of incision extended from an inch or so above the external malleolus to near the base of the metatarsal bone of the fourth or ring toe, crossing the most prominent part of the astragalus. The tendo Achillis was always sectioned. No vessel required ligation. The peronei tendons were not involved in the operation. A few strands of catgut were inserted in the wound to secure drainage. Strict antiseptic precautions were observed before, during, and after the operation. The limb was placed upon a right angle tin splint and kept elevated for at least a day or two. Immediate union followed. The primary dressings were not disturbed until the end of the third, generally the fourth week.

Although, perhaps, sufficient time has not yet elapsed to give a positive opinion as to all of these cases, yet, so far, the results have been more satisfactory than in any former operation for similar deformities in my experience. I believe that we have a better right to expect permanent correction of the deformity after the operation of excision of the astragalus, from the fact that the cause of the obstruction is removed, so that the foot can be brought to a right angle, and the whole of the sole of the foot can be normally placed upon the ground when the patient stands upon it. The motion of the joint is also increased by the removal of the bony wedge which

interfered with flexion. If I have correctly appreciated the pathology of these cases, I think we are warranted in claiming that, by the means proposed, better and more permanent results will be obtained than by any other method which has been proposed for the relief of these complicated forms of club-foot.

It is well, however, to bear in mind that, no matter what form of operation is performed for the correction of talipes, nor how perfect may be the immediate result, the disposition to recurrence of the deformity will continue for a long time from the persistent, unequal muscular action, which demands watchful care to insure a permanent successful result.

Discussion.—Dr. De Forest Willard, of Philadelphia: So far as the ease of the operation and its efficacy of removal of the astragalus in the correction of the deformity in extreme cases of club-foot are concerned, I can agree with Dr. Morton. We should, however, be guarded in the application of this operation to young children under three years of age. It has been my experience, in partial dislocation of the astragalus in young children, to force the astragalus into position. Even in the older cases approaching the inveterate condition, the application of extreme force, with subcutaneous division of all contracted tissues, will often bring the foot perfectly flat on the ground and place the foot at right angles with the leg. If these results cannot be accomplished in this way we must excise bone, take out the astragalus, and do whatever is necessary to bring the foot into the proper position.

Dr. Charles T. Parkes, of Chicago: My experience in the last few years includes thirty-eight cases of club-foot, varying in age from four months to eighteen years. I regard the proposed operation as unnecessary. The method which I have employed has been that of forcible rupture. It sometimes requires the entire strength of the operator to bring the foot into good position. After all resistance has been overcome, the foot is fixed in an over-corrected position and a plaster dressing applied. This apparatus should be applied over two pairs of stockings, the inner of which should be of silk. It is sometimes necessary to repeat the breakage two or three times. The patient is allowed to go about on the plaster case, and it is renewed as necessary. I have not found tenotomy or division necessary.

Dr. J. Ford Thompson, of Washington: I have tried all the various plans of treatment suggested, with varying results. In those cases which do not yield to manipulation or which recur, we should cut everything that is tight. I do not see why such great force should be used when a simple subcutaneous section will relieve the contraction. Force is necessary even after section. I believe that there is a number of cases requiring tarsectomy or excision of the astragalus; I believe that both these operations are well established.

Dr. Thomas G. Morton, of Philadelphia: In the cases in which I have excised the astragalus, the bone has had no relation whatever to the joint. It was completely dislocated, and Dr. Willard's remark in regard to forcing the astragalus back could not apply in these cases. In order to bring the foot to a right angle and to make a useful joint, it is necessary to get rid of the wedge formed by the displaced astragalus. I condemn the use of plaster-of-Paris entirely, for it prevents the necessary massage and attention to the development of the muscles.

Dr. John E. Owens, of Chicago, exhibited an emergency case, containing all the instruments and appliances likely to be needed in the first treatment of a case of accident.

(To be continued.)

This is the season for society meetings, and every man with a paper is sure to be heard.

American Medical Association.

FORTY-FIRST ANNUAL MEETING.

Held at Nashville, Tenn., May 20, 21, 22, and 23, 1890.

(By telegraph to the Medical Record.)

First Day, Tuesday, May 20th—General Session.

The forty-first annual meeting of the American Medical Association opened at eleven o'clock in the Vendome Theatre. The main body of the theatre, having a seating capacity of over a thousand, was more than filled by the members, the private boxes and unfilled portions of the galleries being occupied by the wives and daughters of the delegates.

The meeting was called to order by Dr. W. T. Briggs, chairman of the Committee of Arrangements.

He introduced the Rev. R. R. Wetherspoon, pastor of the First Presbyterian Church of Nashville, who offered the opening prayer.

Then Dr. Briggs delivered an address of welcome on the part of the physicians of the State. "Delegates have come," he said, "from every State in the Union to confer together here, and to renew the obligations which they had taken upon themselves when they were enrolled in the ranks of the medical profession. They had come inspired by no sordid motives, but each anxious to contribute his share to the common treasury of scientific facts. One-third of a century ago the Association met in Nashville, then a city of some twenty thousand, instead of the hundred thousand inhabitants of which it could now boast, but the Association had grown also, and many times as many members had already registered in the first few hours of the session as had constituted the entire attendance in 1857." He greeted the members in behalf of the profession of this State and city, and he promised that when they departed their hands would ache from the strong grasp of Southern hospitality.

Address of Welcome.—In the absence of Governor Taylor, the address of welcome on the part of the State was delivered by State Senator Craighead. He said that this call found him so totally unprepared that he could do no more than extend to all the most cordial welcome that one of the representative States of the Old South could offer. He emphasized the word old because he claimed that it was truly the Old South, and that its present prosperity was due, not to the brains and capital of the North, but was the result of Southern energy, born of necessity.

This speaker was followed by Mayor McCarver, who welcomed the members of the Association on the part of the city of Nashville.

Necessity of National Control in Sanitary Matters.—Dr. Briggs then introduced the president, Dr. E. M. Moore, of Rochester, N. Y., who delivered his annual address. He chose for his subject the necessity of national control in sanitary matters. Hygiene does not receive in this country the attention which it deserves. A certain foreigner once said that Americans cared little for health, and when they lost it they took pills. He was in great measure right, as is shown by the fact that medical men are still therapeutists rather than hygienists. Yet we have no cause to despair, for we are progressing, slowly though it may be, in the right direction. In proof of this assertion the speaker reviewed at considerable length the history of Congressional legislation on sanitary matters since the passage of the first act of that nature in 1796. This act directed the President of the United States to assist the State governments in the execution of the quarantine laws enacted by their respective Legislatures. This was followed at infrequent intervals by other similar laws, their execution, however, being intrusted to the Secretary of the Treasury instead of to the President. This was done because it was this department that was specially affected by the enforcement of quarantine. When State boards of health were first

established they met often with great opposition, but when epidemics came the local boards were found in many cases unprepared to cope with them and then the utility of the State boards was demonstrated. It was through the instrumentality of the latter that the local boards were spurred into activity. But the boards in the different States varied much in their powers, and some States even yet have none, hence arises the necessity for central authority in matters of this nature. Epidemics are not confined to single States, and they can be controlled only by an efficient body having authority to force its measures in all the States. The National Board of Health has a glorious record, and it has seldom fallen to the lot of any association to demonstrate in so short a time its utility. The recommendations embodied in the report of this board are still reliable, and are of use in sanitariums.

Dr. Moore then reviewed the evolution of the Marine Hospital service since its establishment in 1798 to care for sick sailors into virtually a department of the general Government. He spoke of the excellent sanitary work which it did during the prevalence of yellow fever in Florida, and dwelt upon the vast superiority of such a land quarantine station as Camp Perry over the shotgun quarantine usually established by individual communities in the absence of any intelligent and authoritative control.

The work of the Department of Agriculture in restraining the spread of pleuro-pneumonia among the cattle throughout the country, and in studying by modern bacteriological methods the diseases most common among swine, was then referred to. But the control of disease among cattle was not properly the duty of the Secretary of Agriculture any more than disease among men was part of the duty of the Secretary of the Treasury. The minister of finance was not the proper person to protect the health of the community. Disease was like an invading host, and, like such an enemy, was to be opposed by an army. It was customary to speak of the work of sanitary officers as police duty, but it was rather military, and sanitary officers should have military powers. The speaker hoped that the time was not far distant when there would be a bureau of sanitation at the seat of the central Government, whose head should be a cabinet officer. The subordinates under his control should have a sure tenure of office, such as is secured by a commission in the army and navy. He did not think it expedient that this secretary of public health should be a physician any more than the Secretary of the Navy need be a sailor, or the Secretary of War an army officer.

At the conclusion of the address a vote of thanks was extended to the President, with the usual recommendation that the address be published in the Journal of the Association. It was also moved and carried that the suggestions made by the speaker be referred for consideration and elaboration to a special committee.

SECOND DAY, WEDNESDAY, MAY 21ST.

The general session was called to order by PRESIDENT MOORE at 10 A.M.

Prayer was offered by REV. DR. WINCHESTER, Pastor of Christ Church.

The elections to the Nominating Committee were announced.

It was then voted that the title of the Section in Medical Jurisprudence be modified by adding the word Neurology, so that subjects belonging to this specialty might be there discussed. It was also decided to elect a vice-chairman as well as a chairman for each section.

The Address on General Medicine was then delivered by DR. N. S. DAVIS, of Chicago. It was a plea for the abandonment of the reckless use of alcohol and of antipyretics, and especially of the newly introduced synthetic remedies in the treatment of febrile affections. Clinical experience amply proved that their action in reducing fever was but a temporary one, that it was necessary to administer them again and again in order to obtain any continuous antipyretic effect; yet at the present day so great was the dread of high temperature that much of the bedside treatment of disease has become little more than a chemical process.

Treatment of Fevers by Antipyretics.—Practitioners directed all their efforts to the reduction of fever and paid but little attention to the condition of the secretory and excretory functions or to the vital changes liable to take place in the various organs of the body. If fever were the disease and local lesions were only accidental accompaniments of it, then would a specific antipyretic course of treatment be rational. But this is not the case, and it is found that the reduction of temperature does not cure the disease.

Dr. Hood has recently published some statistics of London hospitals which corroborate this assertion. Of over two thousand febrile cases noted, twelve hundred had been treated after the introduction of these new antipyretics; but it was not found that the course of the disease was abbreviated, or that untoward complications and sequelæ were prevented. The value of a remedy in the treatment of an acute general disease must be determined not by its temporary control of one or two prominent symptoms, but by its effect upon the course of the disease as a whole. It has been abundantly proven that these new antipyretics diminish heat production by preventing tissue changes, and by their action on the nerve-centres, and do not lower the temperature by promoting the elimination of heat. They interfere with the functions of the corpuscular element of the blood, as is well shown by the cyanosis which follows their use, and the marked analgesic properties which they possess demonstrates the fact of their action upon the medullary centres. Experiments have furthermore shown that the urea and other constituents of the urine are decreased by the administration of these synthetic antipyretic remedies, but this can come only from interference with most important molecular actions upon which heat production and elimination depend. These drugs find their application in the early stages of sthenic fevers accompanied by pain—in acute rheumatism, for example. But in low forms of continued fever their continued administration can be productive only of harm, interfering with the natural course of the disease, tending to increase the debility and retarding convalescence.

Alcohol in Continued Fevers.—Dr. Davis then spoke of the use of alcohol in the treatment of continued fevers, claiming that its action was similar to that of the internal antipyretics. It diminishes nervous sensibility, reduces temperature, and retards molecular changes. The assumption hitherto has been that alcohol must undergo oxidation in the body, but experiments have shown that this theory is erroneous. He then quoted the statistics of many hospitals in which alcohol was used in the treatment of typhoid fever and pneumonia, and compared them with those of his own wards in Mercy Hospital, Chicago, and of those institutions where alcohol was not given in these diseases. The result of this comparison showed that the mortality from pneumonia and typhoid fever was very much lower in hospitals where alcohol was not employed in their treatment.

In conclusion he said that we must as early as possible remove a patient suffering from a continued fever from the further action of the specific poison. As the living animal organism tends to destroy this poison by its own metabolic changes, we must carefully avoid the use of such remedies as retard those changes and give those which will increase them, as there is a retardation of heat elimination we must increase this by means of the sponge-bath or of the cold pack, both of which exert an extraordinary influence for good. As every specific cause capable of producing fever has a tendency to induce morbid changes in some of the bodily organs, we must early and carefully use remedies whose effect is to

abolish or modify those local developments. Finally, as all acute morbid processes are progressive and have a course marked out by distinct stages, we must adopt our remedies to the different periods of the disease, remembering that what is useful in one stage may be injurious in another. Specific remedies can be of service only in the earliest stages of disease. Indeed, the antiseptics are useful in prophylaxis rather than in the therapeutics of disease.

At the conclusion of the address a vote of thanks was extended to Dr. Davis.

The Rush Monument.—The report of the Rush Monument Committee was then read. It was not of a very encouraging nature, the treasurer stating that but a little over three hundred dollars had been collected during the year, the total amount available for the erection of the monument being less than fifteen hundred dollars. Dr. Gihon hoped on, however, and looked forward to the laying of the corner-stone in Washington during the meeting of the Association in that city in 1892.

The Journal of the American Medical Association.—The report of the Trustees of the *Journal* was then read. It showed an increase in the circulation, the number of subscribers being now 4,570.

Third Day, Thursday, May 22d.

After the meeting had been called to order by Dr. Moore prayer was offered by Rev. Dr. Cave, pastor of the Christian Church.

The Committee on Nominations then made a report recommending the following officers for the ensuing year: *President*, Dr. W. T. Briggs, of Tennessee; *First Vice-President*, Dr. C. A. Lindley, of Connecticut; *Second Vice-President*, Dr. R. C. Moore, of Nebraska; *Third Vice-President*, Dr. H. C. Wyman, of Michigan; *Fourth Vice-President*, Dr. L. P. Gibson, of Arkansas; *Treasurer*, Dr. R. J. Dunglison, of Pennsylvania; *Secretary*, Dr. W. B. Atkinson, of Pennsylvania; *Librarian*, Dr. C. L. Richardson, of District of Columbia; *Address on Medicine*, Dr. E. L. Sherman, of Michigan; *Address on Surgery*, Dr. J. M. Mathews, of Kentucky; *Address on State Medicine*, Dr. W. L. Schenck, of Kansas. The place of the next meeting was designated as San Francisco, and the time the first Tuesday in May. An amendment to the report was offered substituting the name of Washington, D. C., in place of San Francisco. A second amendment was offered substituting the name of Omaha, and a most eloquent presentation of the claim of the latter place was made by a delegate from the Omaha Medical Society. This amendment was lost. Then the amendment substituting Washington for San Francisco was carried nearly unanimously. The report of the Committee as amended was then accepted.

The Address in Surgery.—The Address in Surgery was delivered by Dr. Samuel Logan, of New Orleans. The science of medicine, he said, had made greater advances during the last fifty years than in many centuries before, and it was particularly in the department of surgery that this advance had been most striking. Facts constituted the cases in which progress had been made, and these were found recorded in the proceedings of medical societies and medical journals. The author reviewed the recent literature discussing the relative safety of chloroform and ether in general anæsthesia, and gave rules governing the method of administering these agents. Chloroform should be given largely diluted and very gradually, while ether should be given rapidly and almost undiluted.

Chloroform Narcosis.—The author did not presume to settle the dispute whether in chloroform narcosis there was first respiratory failure or cardiac failure; nor whether the one or the other of the two generally used anæsthetics was the safer.

Antiseptic Surgery.—A brief review was further given of recent advances in antiseptic surgery, the speaker referring especially to a paper in the report of the Marine Hospital Service, in which it was shown how easily a wound might be infected by micro-organisms imprisoned beneath the finger-nails of the hospital nurse as well as of the surgeon.

Various reports of the Secretary, Treasurer, etc., were then presented.

(To be continued.)

Correspondence.

UNCONSCIOUS MONONYMIZATION.

To the Editor of the Medical Record.

Sir: The not uncommon unintentional simplification of anatomical terms by the reduction of the adjective to a prefix, is exemplified in Dr. James Hendrie Lloyd's diagram of an "Anomaly of the Circle of Willis."[1] The left posterior cerebral artery is designated by L. Post Cerebral; the C is a capital, but between it and the *Post* is neither hyphen nor period. The complete series of steps from a polyonym to a mononym would run as follows: 1, Posterior Cerebral; 2, Post. Cerebral; 3, Post-Cerebral; 4, Post Cerebral; 5, Postcerebral.

Such locative mononyms cannot possibly mislead; in like manner, the dionym middle cerebral is reduced to medicerebral, without ambiguity; anterior cerebral becomes precerebral, but the adverbial prefix could hardly be mistaken for anything else than the adjective in question. Analogous terms are Owen's precava and postcava, prefrontal, postfrontal, and medifrontal; the writer's precommissure, postcommissure, and medicommissure, prepeduncle, postpeduncle, and medipeduncle, and the almost universally employed names of certain encephalic segments, *e.g.*, mesencephalon and prosencephalon. An admirable series of locative mononyms may be seen in Dr. William Browning's article, "Vessels of the Brain," on page 232 of the last volume of Wood's "Reference Handbook of the Medical Sciences."

Burt G. Wilder.

IT MAY HAVE BEEN DUE TO COCAINE.

To the Editor of the Medical Record.

Sir: In your issue of May 10th Dr. W. F. Chappel contributes an interesting article entitled "Neurasthenia and Neuralgia from Traumatism of the Nasal Passages."

It seems to me quite possible that many of the symptoms so well described by Dr. Chappel as occurring in his cases following operations upon nasal tissues may be better accounted for by the cocaine which he speaks of using freely in one case, and which it is perhaps fair to assume was used in all. There is certainly a tendency in some patients to become profoundly impressed by even small quantities of cocaine.

In my own hands I have often found the temporary anæsthesia too dearly bought by an intense pain, lasting for hours, or even days, and which I could only account for as being due to the anæsthetic.

In one case the application of a four per cent. solution to the uvula was followed by a most intense pain in the palate and teeth, which lasted for two or three days, and which the patient described as resembling the pain of a frozen member "thawing out."

In a cervix operation there was more pain following, and lasting for several days, than I had ever experienced before or have encountered since. I have had the same experience from the application of cocaine to the female urethra before dilating, and the cervix before curetting.

In cases, too, operated upon by rhinologists, to whom they had been referred by me, the after-pain has seemed to me to have been so out of proportion to the extent of the operative procedure that I have been forced to explain it upon some other hypothesis; and I feel quite

[1] Journal of Nervous and Mental Diseases, April, 1890, p. 225.

convinced that much of the suffering following operations upon the nose is due to the cocaine applied as an anæsthetic; and that many of the symptoms detailed in Dr. Chappel's cases may be similarly accounted for.

That in many cases cocaine may be used with impunity is, no doubt, true; but there are, I am certain, many whose nervous systems are profoundly impressed by it, and whose sensory nerves take their innings, after an enforced idleness, with a cruel intensity.

S. S. Jones, M.D.

809 Lexington Avenue, New York.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 11 to May 17, 1890.

By direction of the President, the Army Retiring Board convened at Fort Leavenworth, Kansas, by War Department order, dated May 10, 1887, published in Special Orders, No. 107, May 10, 1877, from Headquarters of the Army, is dissolved, and War Department order, dated April 26, 1890, published in Special Orders, No. 99, April 28, 1890, from Headquarters of the Army, directing Captain John de B. W. Gardiner, Assistant Surgeon, to report to the President of the Board for examination, is revoked. S. O. 111, par. 10, A. G. O., Washington, D. C., May 12, 1890.

By direction of the President, and in accordance with Section 1,246, Revised Statutes, an army retiring board was appointed to meet at the War Department, in this city, at 11 o'clock A.M., on Wednesday, May 14, 1890, for the examination of such officers as might be ordered before it. Detail for the board: Lieutenant-Colonel Anthony Heger, Surgeon; Major Charles R. Greenleaf, Surgeon. S. O. 110, par. 6, A. G. O., Washington, D. C., May 10, 1890.

Forwood, William H., Major and Surgeon. By direction of the Secretary of War relieved from duty at Fort Snelling, Minnesota, and will report in person on the 27th instant to the Governor of the Soldier's Home, District of Columbia, for duty as attending surgeon at the Home. S. O. 113, par. 11, A. G. O., Washington, D. C., May 14, 1890.

Cronkhite, Henry M., Major and Surgeon. By direction of the Secretary of War relieved from station at Little Rock Barracks, Arkansas, and assigned to duty at Port Lewis, Colorado, at which post he is now on temporary duty. S. O. 113, par. 10, A. G. O., Washington, D. C., May 14, 1890.

Mason, Charles F., First Lieutenant and Assistant Surgeon, now on leave of absence, by direction of the Secretary of War, will report in person to the commanding officer of Fort Logan, Colorado, for temporary duty at that station. S. O. 113, par. 7, A. G. O., Washington, D. C., May 14, 1890.

Byrne, Charles C., Lieutenant Colonel and Surgeon. By direction of the Secretary of War, leave of absence for four months is granted, with permission to go beyond the sea, to take effect on or about June 1, 1890. S. O. 110, par. 3, A. G. O., Washington, D. C., May 10, 1890.

Cherbonnier, Andrew V., Captain and Medical Storekeeper. By direction of the Secretary of War, leave of absence is granted from June 1st, to include October 10, 1890. S. O. 110, par. 4, A. G. O., Washington, D. C., May 10, 1890.

Ewing, Charles B., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Washington Barracks, District of Columbia, and will report in person to the commanding general, Department of the Missouri, St. Louis, Missouri, for duty as attending surgeon at those headquarters. S. O. 110, par. 8, A. G. O., Washington, D. C., May 10, 1890.

Johnson, Henry, Captain and Medical Storekeeper, now on duty at the Medical Purveying Depot, New York City, by direction of the Secretary of War, will take charge of that Depot, and perform the duties of Colonel Edward P. Vollum, Surgeon and Acting Assistant Medical Purveyor, during the absence of the latter. S. O. 109, par. 11, A. G. O., Washington, D. C., May 9, 1890.

Vollum, Edward P., Colonel, Surgeon, and Acting Assistant Medical Purveyor. By direction of the Secretary of War, leave of absence for two months is granted, to take effect June 1, 1890, with permission to go beyond the sea. S. O. 109, par. 10, A. G. O., Washington, D. C., May 9, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 17, 1890.

Mackie, B. S., Surgeon. Ordered to the Practice Ship Constellation, May 15th.

Lowndes, C. H. T., Assistant Surgeon. Ordered to the Practice Ship Constellation, May 15th.

Fitzsimons, Paul, Surgeon. Detached from the Marion, and ordered home.

Martin, H. M., Surgeon. Granted six months' leave of absence to leave the United States.

Horwitz, P. J., Medical Director. Granted nine months' leave of absence to leave the United States.

Wentworth, A. R., Passed Assistant Surgeon. Resignation accepted, to take effect November 14, 1890.

Herndon, C. G., Passed Assistant Surgeon. Detached from the Enterprise, and to wait orders.

Gihon, A. L., and Kindleberger, David, Medical Directors. Appointed Delegates to represent the Medical Department of the Navy at International Medical College, Berlin, Germany, August 4, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 17, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	4
Scarlet fever	78	8
Cerebro-spinal meningitis	2	4
Measles	392	37
Diphtheria	108	31
Small-pox	0	0
Varicella	10	0
Cholera	0	0

Excretion of Mercury through the Salivary Glands.—At a recent meeting of the German Medical Society of this city, Dr. Weiss reported a case of mercurial salivation in which the greater part of the mercury was elimin ated by the salivary glands, contrary to the general rule.

What is the Difference?—There are to be various congresses of women engaged in different pursuits in Chicago at the time of the World's Fair. In describing what would be done in this direction, one of the committee referred to the members of the different professions as women doctors, female nurses, and lady lawyers.

For the Relief of Earache.—Take five parts of camphorated chloral, thirty parts of glycerine, and ten parts of oil of sweet almonds. A piece of cotton is saturated and introduced well into the ear, and it is also rubbed behind the ear. The pain is relieved as if by magic, and if there is inflammation it often subsides quickly.—*Medical Brief.*

THE PLACE OF STATIC OR FRICTIONAL ELECTRICITY IN MEDICINE.

BY WILLIAM JAMES MORTON, M.D.,

NEW YORK CITY.

ALTHOUGH I do not care to come forward as a special champion of static electricity in therapeutics, using, as most physicians do, all means at command which I think will cure, still I cannot avoid a certain degree of responsibility in relation to its use, since its introduction in modern form into medical practice, in the United States, followed the reading of a paper by myself before the New York Academy of Medicine, on March 3, 1881, and the exhibition of machines and electrodes which I brought from Paris and furnished as models to manufacturers here.

Struck by its merits and its efficacy, as exhibited at Professor Charcot's clinic, I introduced it to the profession in a public way here in America, with a conservative desire to test its merits and have others do so.

Nearly ten years have elapsed; the therapeutic use of static electricity has extended enormously in medical practice, and it is to be expected that an effort should now be made to ascertain its rightful value. I read, therefore, with great interest, an account of the proceedings of the Academy of Medicine, published in the MEDICAL RECORD last spring,[1] relating to "The Place of Electricity in Therapeutics."

The reader of the paper of the evening, Dr. M. Allen Starr, argued that the attainable curative results of electricity were disappointing, and that static electricity was particularly inefficacious. The general subject was ably discussed, but the special attack upon static electricity has not yet been specifically answered. In a broad way I most heartily agree with the reader's opinion, shared to-day with a multitude of workers in electro-therapeutics as a whole, that electricity has not come up to the claims made for it. But is not the real trouble with the claims, and not with the agent? If the effort to cure all disease by electricity is disappointing, is it not equally so by medicines or other treatment? Is not the progress of medicine mainly distinguished by increased familiarity with the natural history of disease and its prevention or avoidance, and by the discovery and use of new drugs and means to relieve symptoms, mainly pain? To cure organic disease by remedies is yet apparently in a most backward state. Yet this has been expected of electric ity, hence disappointment.

But if, in place of expecting to cure a profound and established organic disease, we turn our attention to symptomatic and functional treatment, to the treatment, among other things, of pain, spasm, anæsthesia, hyperanæsthesia, paralysis, and to nutritive faults, we may still have cause to find that electricity holds a pre-eminent place in medicine. The real question is, What is its value relatively to other therapeutic agents?

This, however, is a digression from the main point of this communication, which is to courteously take issue with Dr. Starr as to his statements concerning the effect of static electricity in particular upon the human body. And to understand his position more fully, we may supplement his views appearing in the RECORD by reference to similar views expressed by him in *Scribner's Magazine* for November, 1889, in an article entitled "Electricity in Relation to the Human Body."

If what Dr. Starr puts forward as facts in regard to frictional or static electricity is true, then I most cordially admit that this form of electricity has no place in medicine. But it is precisely that his statements of fact have no foundation that I think it worth while to point this out, lest, unanswered, they may be accepted as authoritative.

Having stated the well-known observation that electricity at rest, or "static" electricity, resides on the surface of bodies which are charged with it, and having quoted the famous Cavendish or Biot experiment of the insulated sphere and its removable caps to demonstrate this very general statement, Dr. Starr states that the same is true of the human body, and "therefore frictional electricity never penetrates beneath the skin, nor produces directly any effects upon the deeper tissues," though the "giving of the sparks causes a decided irritation of the surface" and produces "indirect effects," such as reddening and a conscious perception, as between the spark and the breeze or spray, that the one is disagreeable and the other agreeable; and also a sudden movement of the irritated part, as, for instance, "one suddenly draws one's hand away from a lighted cigar before one realizes what is touched."

"But the same kind of indirect effects," he continues, "may be produced by any mild irritation of the skin. The general effect of static electricity is, therefore, about the same as that of a cold bath, or the muscle-beating of the Swedes, the lomi-lomi of the Sandwich Islanders, the whipping with twigs in a Russian bath, the needle douche of a Turkish bath, or any other sharp mechanical irritant."

And again. "It seemed strange how much credence was still given static electricity in therapeutics, for its action was limited exclusively to the surface of the body charged; it did not penetrate the skin, could not permanently charge the body, and could produce a curative effect only as a surface irritant or by reflex action." All this, of course, while giving sparks, for this method of administration is assumed or referred to as the one producing the indirect effects, and failing to produce anything more. This is indeed a severe arraignment of static electricity in medicine, and, if true, leaves it no ground to stand upon.

We will meet the situation at once by direct experiment, and by pointing out the incredibility of the statements according to the laws of electro-physics. The main points at issue are covered in by the statement that "frictional electricity never penetrates beneath the skin, nor produces directly any effects upon the deeper tissues," and that its "action is limited exclusively to the surface of the body charged."

A speedy refutation of the exclusive superficial action claimed is found in the following simple experiment: We place in the hand of a fairly muscular subject, standing upon the insulated platform, a weight, say of ten pounds (an Indian club is preferable, since the nearness of a metal weight weakens the spark), and causing him to raise it until his arm is at right angles, we administer a single and ordinary spark to the motor point (or almost any point) of his biceps muscle. The weight is raised half an inch or more, and by successive sparks we may vibrate the weight in unison with the spark. Query: Has not the frictional electricity "penetrated the skin" and

[1] MEDICAL RECORD, April 6, 1889.

caused an "effect upon a deeper tissue," viz., the biceps muscle?

Careful efforts with twigs, douche, cold baths, lomi-lomi, and nearly all the agents mentioned as having "about the same general effects as static electricity," failed in our hands to elicit any visible contraction of the muscle and raising of the weight, and we conclude, what is well-known, that the effects are not comparable except in a most remote manner.

Again, while the subject is seated in a chair upon the platform, we lay a twenty-pound dumb-bell upon the thigh, half-way between the groin and the knee, and give a spark to the motor point of the vastus externus muscle. The dumb-bell is raised half an inch, and this, too, by the bellying or bulging of the muscle, and not by direct pull. The same effect will be produced even if we give the spark to the dumb-bell itself, well illustrating the principle which is at the bottom of all this stimulation of nerve and muscle, viz., that static charge in the act of discharge becomes kinetic, current, or flowing, and traverses the human body as it would any other conductor.

Let us for one moment pause to consider the amount of work done by the spark:

One pound raised 1 foot in 1 second equals 1 foot-pound.
One pound raised $\frac{1}{2}$ inch in 1 second equals $\frac{1}{24}$ foot-pound.
Twenty pounds raised $\frac{1}{2}$ inch in one second equals $\frac{20}{24}$ foot-pound, or, say 1 pound.

A single spark therefore represents a muscular energy expended equal to raising 1 pound 1 foot per second. But I can easily give, say, 5 sparks per second. The muscle therefore raises 5 pounds per second, and to raise 550 pounds (the unit of horse-power) will require 110 minutes, or about 2 hours. The actual work, therefore, capable of being accomplished by the muscle under the stimulus of the spark is at the rate of 1 horse-power every 2 hours, or $\frac{1}{2}$ a horse-power per hour.

That this estimate is very moderate will occur even to our critic, since he himself writes that "the amount of energy in the spark is proportionate to the expenditure of energy in friction." This may be demonstrated experimentally by placing two machines opposite to one another, pole to pole, and turning one when the second will itself begin to turn. In treatment, the product of the machine expends itself upon the patient in a manner to be mentioned later on, and if the man-power turning the crank be resolved into units of horse-power, the above showing would be much increased.

And what is accomplished by a single little spark with the biceps and the vastus externus, may be accomplished with practically every muscle in the body. A spark to the deltoid throws the arm out from the side of the body, and, what is equally interesting, throws the entire shoulder group of muscles into contraction, so deep and widely diffused is the effect. Thus, also, a spark to the anterior region of the thigh will throw its entire mass into contraction. Each smaller muscle may be sought out and caused to contract just as it would, under similar circumstances, by the interrupted galvanic or the faradic current.

All this seems too trite to say; everybody who has used static electricity knows it, and it is certainly a most interesting neurological anomaly to have denied it.

Dr. Starr seems to have confounded, as I have already intimated, frictional electricity at rest with the same in motion—in the former state truly "static," in the latter "kinetic," or flowing in conductors, and most powerful to stimulate nerve and muscle and produce contractions, as well as to excite nerves of special sense.

Physiologically as well as in practice, it is well known that the muscular tissue is exceedingly sensitive to the feeblest discharges of static electricity. The sparks of a distant frictional machine set the frog's legs in contraction which drew Galvani's attention to the new form of electricity.

And again, the Abbé Nollet [1] convulsed the arms and shoulders of an entire regiment of 1,500 men by causing them to join hands in line, and then completing the circuit by a spark of static electricity from a Leyden jar, just as in our present methods of administration, except that we do not require as strong an application. The ordinary ball electrode represents one tinfoil coating of the jar, the air the glass dielectric, the charged person the other coating; when the discharge or spark occurs the differences of potential are equalized by an instantaneous flow of electricity throughout all portions of each charged conductor, and if the electrical continuity of our tinfoil coatings happen to be extended to a regiment of men or to the biceps muscle, the effect will be to "penetrate the skin" and affect deeper tissues.

That frictional electricity, when static, resides upon the surface is one way of making the statement. To avoid argument we will admit it. We will say, then, that the person sitting upon the insulated stool receives the electric charge upon the surface.

But while bringing forward one fundamental law of electricity, Dr. Starr ignores another one equally fundamental, which is that the potential at all points of a conductor on which electricity is at rest must be uniform; if it were not, there would be a flow between the two unequal potentials until it became uniform; hence the potential inside a conductor has the same value as at any point on the surface.

It follows that at the moment of discharge (spark) the equalizing of the potentials proceeds from and to all parts of the conductor (human body), inside and outside, and we here have the current which produces the effects on nerve and muscle. And the conducting power of the charged conductor is proportional, not to the surface, but to the mass of the conductor, for a solid rod of a given diameter will convey a current which would melt a thin tube of the same diameter.

Given, then, a surface charge upon the body, and the first spark changes the entire situation. The spark is a current, but it is only the air part of the current—the evidence of the breaking down of the strain in the fluid dielectric; the remaining continuity of the current is *in* the patient's body, not *on* it (for the potential is uniform), in the chain going from the platform to the machine, and so on up to the initial electro-motive force of the Holtz machine, and around again in a closed circuit to the ball electrode which gave the spark. The conditions do not vary essentially from those existing in a galvanic cell or a storage battery. When we close the circuit we get the current, and it is this current which, localized by an electrode, traverses the human body at any desired point—a current of, say, 50,000 volts as against 1 volt of a Daniels's cell—put to work to overcome the resistance of, say, 2,500 ohms of the body; a resistance so trivial in comparison with the voltage or pressure that it may be disregarded entirely—a current oscillating (alternating) 100,000 to 1,000,000 times per second, compensating, as regards its physiological activity, for its loss in quantity, by its enormous electro-motive force and by its exceeding rapidity. The wonder would be that nerve and muscle and all tissues should not be stimulated. The fact is that they are. And Dr. Starr's entire structure, based upon static charge, falls to the ground in the light of the discharge and its accompanying current and physiological effects, and he should alter his apparently thoughtless dictum and write, "frictional electricity, as commonly administered, penetrates beneath the skin and produces directly effects upon the deeper tissues."

In conclusion, to leave facts and venture a single opinion, I believe that no form of electricity "penetrates" more deeply than the static; and, premising a powerful machine, a powerful spark, a conservative expectation as to results, a fair comparison with galvanism and faradism, an intelligent selection of cases, and a fair amount of skill in administration, I believe that no form of electricity equals it in curative effect.

FRACTURES OF THE MAXILLARY BONES. A NEW METHOD OF TREATMENT.

By EDWARD H. ANGLE, M.D.,

PROFESSOR OF HISTOLOGY, COMPARATIVE ANATOMY, AND ORTHODONTIA I THE DENTAL DEPARTMENT OF THE STATE UNIVERSITY OF MINNESOTA.

Muscular contraction is a most difficult obstacle to overcome in reducing and maintaining in proper apposition most fractured bones. Especially in the case of the femur and patella is this force so great, so constant, and so difficult to antagonize, that probably the ideal or normal result is never attained.

In fractures of the inferior maxilla it is equally a most serious hindrance in the way of obtaining a union of the parts, and should always be carefully considered in the construction of an appliance for this purpose; indeed, this obstacle, taken in connection with the large number of movements to which the human jaw is susceptible, and the great number of causes which contribute to the production of these movements, renders this the most difficult bone in the entire human frame to maintain in perfect apposition during the healing process.

This fact is well evinced by the innumerable devices and appliances which have been recommended for the purpose. The methods I have adopted in treating fractures of this bone have been so successful and the results so gratifying, that they seem to approach in efficiency and simplicity more nearly to the ideal than anything yet devised.

In order that this system of treating fractures of the maxillary bones may be more easily understood I will divide these injuries into three classes.

The first class comprises all simple fractures in which the teeth are good and sufficiently sound and firm in their attachments (especially on each side of the fracture), to afford good anchorage for the appliance which supports the fracture.

The second class comprises all fractures where the teeth are unsuited, by disease or any other cause, for anchorage, but are sufficient to give correct articulation of the jaws, when they are in proper adjustment.

The third class comprises all fractures of jaws which are edentulous. The following cases, treated by myself, will enable the reader to comprehend the method peculiar to each class.

Case I. will illustrate the first class. May 29, 1889. Nels ——, aged twenty-one, was admitted to the Saint Anthony Hospital of this city. He had fallen from a pile of lumber, a distance of fifteen or twenty feet, and besides severe bruises, suffered a simple fracture through

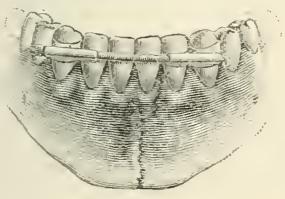

Fig. 1.—Anchor Splint.

the symphysis, terminating, however, in front between the central and lateral on the left side, as shown by the line in the engraving (Fig. 1.). Upon examination I found that the fractured bone was quite widely separated at the top, and that the left central incisor was loosened. The following treatment was practised: First, the ends of the fractured bones were placed in their proper position and temporarily fastened by lacing the teeth with silk ligatures.

Second, bands of very thin German silver were made to encircle and accurately fit the cuspid teeth. A small tube of German silver, one-half inch in length, was soldered to each band and in exact alignment; a piece of wire accurately fitting the bore of these tubes, bent at right angles at one end, and having a screw cut upon the end was slipped through each tube and secured therein by adjusting a nut on the screw. The bands were cemented in position upon the teeth by means of oxy-phosphate cement, as shown in Fig. 1. After the cement had become thoroughly set, the nut was tightened until the fractured ends of the bone were drawn snugly together.

These bands, tubes, wires, screws, and nuts are some of the appliances known as the "Angle Regulating and Retaining Appliances" devised and used for the purpose of correcting irregularities of the teeth, as shown in Fig. 2. They may be made by any ingenious dentist, or procured from any dealer in dental goods.

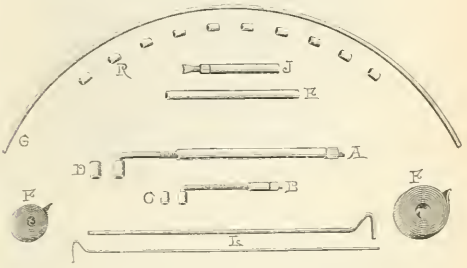

Fig. 2.—Angle's Regulating and Retaining Appliances.

The appliance was worn without displacement or trouble for twenty-one days, when it was removed, the bone having become firmly united. I may add that, during the time the appliance was worn, so firmly was the jaw supported, the patient suffered little if any inconvenience, and, after the third day, partook regularly of his meals, using his jaw freely, and only avoiding the hardest particles of food. After removing the appliance a careful impression of the jaw was taken, a model made, and the appliance transferred to the model, exactly as shown in the engraving. The lower part of the jaw is, of course, diagrammatic, as added by the engraver to show the line of fracture.

It should be borne in mind that the principle upon which this appliance is based is not the same as that which is operative when the teeth are simply wired together. It is very different. For in wiring, the upper part of the fracture only is tipped or drawn together, and no pressure or support is given to the lower part; while in the principle applied here, it will be seen that, because the bands and pipes are rigidly attached to the anchor teeth, tipping is impossible and pressure is exerted equally upon both parts (upper and lower) of the fracture, as they are drawn together by the screw; or, as my friend Dr. Charles G. Brown (who first suggested to me this use of the screw), puts it, "It is a Malgaigne splint, if you please, except that the hooks are not foreign bodies." This device may be applied in any locality on either jaw, provided suitable teeth for anchorage be not too remote from the line of fracture. The screw may be bent to accommodate the curve in the jaw should the fracture occur in the region of the cuspid.

Case II.—The method applied to cases of the second class may be understood from the treatment in the following instance: On July 4, 1889, William F——, aged forty-five, was admitted to the Minneapolis City Hospital. A blow from a policeman's club had produced two simple fractures of the inferior maxilla. The first was an oblique fracture of the right side, beginning with the socket of the second bicuspid, extending downward and backward, involving the socket of the first molar, breaking out the second bicuspid and greatly loosening the first molar. The second molar had been lost years before, while the third, as well as the remaining teeth, were much abraded and loosened by salivary calculi, thus making the application of the appliance described in Case I.

impossible. The second fracture was situated on the opposite side high up in the ramus. Because of the swollen condition of the parts, I could not detect the exact line of cleavage, but the grinding of the ends of the bone and the great pain occasioned thereby were unmistakable evidences of a fracture. The patient, as in all such cases, was unable to close the jaws. The fracture on the right side was widely separated and the anterior piece was much depressed by reason of the contraction of the digastric muscle, while the posterior piece of bone was

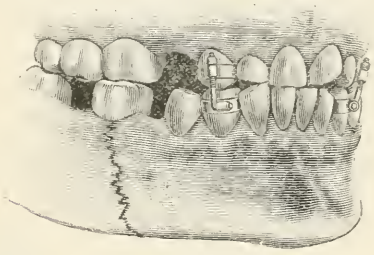

Fig. 3.

drawn firmly up, the molar teeth occluding. The following treatment was used: Bands were made to encircle all four of the cuspid teeth, they being the most firmly attached in their sockets. The fractured ends of the bones were placed in careful apposition, the lower jaw was closed carefully, occluding the lower teeth upon the upper, and requiring so great force and occasioning so much pain, that the use of an anæsthetic became necessary. Points on the bands required for the necessary attachments were carefully noted. The bands were then slipped off the teeth, and little pipes (shown at C, Fig. 2) were soldered at the marked points, after which the bands were cemented in their proper positions upon the teeth, and two small traction screw wires, the same as shown at B, Fig. 2, were slipped into the pipes. The jaws were closed and the nuts tightened on the screws, until the jaws were drawn firmly together, and each tooth occupied its exact normal position in occlusion with its fellow of the opposite jaw. Both fractures were then carefully examined and found to be in perfect apposition, and presented the appearance shown in Fig. 3. How could it be otherwise? for the most natural position for the jaw and the muscles involved had been secured, and all were in their natural places of relaxation and rest.

During an attack of coughing, in the night following, one of the bands was wrenched loose, but was replaced the next day without trouble. No further accidents occurred. The patient readily took nourishment through the spaces between the teeth. Thus the fractured jaw was firmly supported without the least motion for twenty two days, when the appliance was removed, showing most excellent results.

That the patient was a great lover of the clay-pipe was shown by the much worn condition of the lateral incisors, which had resulted from holding the stem of the pipe. While wearing the appliance he was not deprived of his favorite comfort, but was compelled to grasp the stem between the lips instead of the teeth.

Case III.—The following case possesses several points of special interest, although the fractures occurred in regions similar to the case just described, because the appliances, although involving similar mechanical principles, will be found to be greatly simplified.

December 28th Thomas B—— was admitted to the Dental Infirmary of the State University of Minnesota suffering from the effects of a blow received on the left side of the jaw, from a cant-hook, while working in the lumber-camps of Wisconsin, which had produced fracture of the jaw in two places. The first was on the left side, beginning between the first and second bicuspids, and extended downward and backward so far as to involve the lower part of the anterior root of the first molar. The second was on the right side, directly through the angle of the jaw. The fractures had occurred thirty-two days previous to his admission to the Infirmary, during which time nothing had been done to reduce them. He reported that he had called upon a physician, who supposed the trouble was merely an abscessed tooth, and had lanced the gum with the view of reducing the swelling. Later the patient had called upon a dentist in one of the smaller towns, who also failed to diagnose the fractures, and extracted both bicuspids in the hope of giving relief.

Upon examination I found considerable swelling in the region of these fractures, with the usual result, the patient being unable to close his mouth by reason of the fact that the anterior piece of the fractured bone was drawn down by the contraction of the depressor muscles.

Fig. 4.—Angle's Fracture Bands

A false joint had also been established. The bones could be easily worked without causing pain.

At the point of fracture of the right side there was little or no displacement; the swelling was also slight. With the assistance of Professor Leonard, the patient was anæsthetized; the ends of the bones were then rubbed forcibly together with the view of breaking up the false attachments and stimulating activity in repair.

The ends of the bones were now placed in perfect apposition, and the jaw closed, taking great care to articulate the teeth in their correct position against the upper ones.

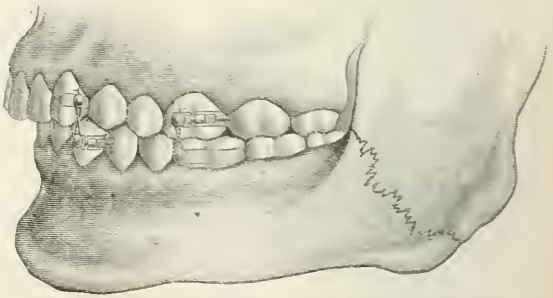

Fig. 5. Fracture Reduced.

The jaw was now firmly bound in this position to the upper teeth in the same manner as described in Case II., only that the method was improved upon by using clasp bands as shown in Fig. 4

No cement was necessary, and, instead of the screws, small metallic buttons were soldered to the sides of these bands (as shown in the cut) around which was wrapped, in the form of a figure eight, fine binding wire, as shown in Fig. 5.

Four bands were used, encircling the four cuspid teeth. Those bands shown upon the molar teeth in the engraving, were not used, but are so displayed for the purpose of illustrating their use in cases which might demand their employment. At the end of seventeen days the bands were removed and the patient discharged, the bone having become firmly united.

It might be urged as an argument against this method that the teeth being closed and the jaws being firmly bound together, the patient would be unable to take sufficient nourishment. This, however, is untrue, for it rarely happens that a patient is found without some teeth

missing, thereby leaving abundance of space for the passage of the liquid foods; and even if all the teeth were sound and in perfect position, it has been proven that there is plenty of space between the teeth and behind the molars and between the upper and lower incisors for taking all necessary nourishment. Of course in such rare cases much more time would be required in taking food; but this obstacle is greatly compensated for by the main points of advantage in its favor, such as (1) cleanliness; (2) comfort to the patient, as compared with many other bulky and awkward appliances; (3) its extreme simplicity, enabling any one, with ordinary mechanical ability, when provided with a set of clamp bands, to easily and quickly set all ordinary cases of fracture; and last (4), the certainty of correct results. These will, I think, be sufficient reasons for all those who are interested in this branch of surgery to give the method a trial.

Cases coming under the third class, comprising fractures of edentulous jaws, are fortunately very rare. The method of treatment I propose in such cases is similar in principle to that already discovered in the first class; only in place of the teeth, small bone-hooks are used; a suitable cavity for their reception being drilled on each side of the fracture, coincident in position with the original sockets of the teeth, as if the implanting of teeth were intended; save that the cavities thus made need not be nearly so large or so deep. They should also be drilled obliquely to correspond to the course taken by the hooks. The hooks before insertion should of course be made aseptic.

INTRA-OCULAR HEMORRHAGE CONSECUTIVE TO CATARACT EXTRACTION OR TO IRIDECTOMY FOR THE RELIEF OF GLAUCOMA.[1]

By HIRAM WOODS, M.D.,

ASSISTANT SURGEON AT THE PRESBYTERIAN EYE, EAR, AND THROAT CHARITY HOSPITAL, BALTIMORE, MD.

Miss T——, aged fifty-six, in robust health, applied to me in June, 1889, for relief from what she termed "sudden loss of sight in the right eye." Examination revealed a mature cataract. Her sudden loss was only a sudden discovery of a loss of long duration. There was good light perception, and the pupil dilated and contracted normally. There was no defect in the left eye. Operation was suggested as the only means of restoring sight to the right eye, but not urged because of the perfect vision in the other. She refused to consider this at all. Her next visit was in August, nearly two months after she first consulted me. She now complained of having had for two or three weeks neuralgic pains in the right eye and temple, for which she had taken quinine. There were present decided premonitory symptoms of glaucoma—a moderately dilated pupil, showing sluggish response to light, and increased tension of the eyeball. The scleral vessels were not enlarged; I greatly regretted not having noted the tension of the eye at her former visit in June. There was then, however, nothing to suggest glaucoma.

The patient could not remember the occurrence of any of the prodromic symptoms prior to her recent attacks of neuralgia. She was urged to have the right eye iridectomized at once, but refused. She was given a solution of eserine (gr. j. to aq. dist. ℥ j.), to be used twice daily. For a fortnight this contracted the pupil, and she did not suffer from the pain in the eye and temple. I could never detect any improvement in the tension of the eye. Early in September her "neuralgia" became severe, and the attacks occurred almost daily. She persisted in taking some neuralgic remedy she had, and declined to listen to advice pointing toward an operation. I did not see her for a week, and during that time she discontinued the eserine. She came to my office on the morning of September 17th. She had no pain then, but had suffered the day previous. The pupil was moderately dilated, with feeble response to light. She now consented to an operation, which I performed at her home the same day, being assisted by my friend Dr. Robert L. Randolph. Before operating I told her the chances of giving her good vision were not great; that the operation might fail entirely to stop the disease, and that the best to be hoped for was that such power of vision as the eye already possessed—minus the cataract—might be retained; that I thought this was probably less than in June she also knew.

An important question was whether or not to extract the cataract with the iridectomy. Provided its removal would not imperil the eye, there were certain advantages in doing both operations at the same time. The patient was exceedingly hard to manage, and very impatient of restraint. She was specially desirous that the cataract should be removed. The case seemed to me to be about this: It was necessary to perform an iridectomy for the reduction of tension; it was desirable to remove the cataract, if it could be done safely. I thought the removal of the lens would effect a greater reduction in tension than would the iridectomy alone, and that this might be of benefit. It also occurred to me that this reduction might be too great, and possibly be followed by intra-ocular hemorrhage—an accident I had never witnessed but had occasionally seen reported. I had given the matter considerable thought before the day of the operation, and had decided that the removal of the lens would not lessen the chances of success for the following reasons:

1. The trouble in the eye appeared to be the old mature cataract, and certain premonitory symptoms of primary glaucoma. There were present none of the conditions which produce secondary glaucoma, and which give the operator a poor eye to start with. The cornea was clear, the anterior chamber was of normal depth, there were no enlarged vessels on the sclerotic, light perception was good, and, although the tension was certainly increased, the eye could not be called "hard." While it was impossible to examine the right retina, that of the left eye was healthy. From this fact and from the clinical history it seemed fair to infer that there was no right apoplectic retinitis—a condition usually thought to make even an iridectomy for glaucoma dangerous, because intra-ocular hemorrhage may occur after the tension has been removed from the diseased blood-vessels.

2. The patient's general health was excellent. There was no organic disease of any kind. The vessels were neither hard nor atheromatous.

3. A little over a year previous there had been a case at the Presbyterian Eye and Ear Hospital which in some respects resembled my own: if anything, it was even more unpromising. One eye showed glaucomatous excavation of the disk, with numerous spots of apoplectic retinitis. In the other there was a mature cataract, with good light perception and increased tension. Professor Chisolm removed the cataract and performed iridectomy at the same time, the patient making an uninterrupted recovery, and obtaining $\frac{2}{0}$ distant vision. These considerations and this observation led me to decide to operate as I did. In the light of the deplorable result they can be easily overruled. At the time, however, they seemed sufficient to justify my course.

The operation was performed after the usual method of cataract extraction. The anæsthetic used was a four per cent. solution of cocaine. The corneal incision was made upward with a Graefe's linear knife. The anterior chamber filled with blood after the corneal incision. I am sure this blood came from the conjunctival vessels. It was easily coaxed out, and the chamber did not fill again. The patient, in spite of being warned to keep still, even if there was a little pain, made a decided jump when the iris was grasped. She was persuaded to keep quiet, and

[1] Read before the Clinical Society of Maryland, December 6, 1889.

the iridectomy was satisfactorily completed. There was no hemorrhage from the iris. The expulsion of the lens was easily effected after cystotomy. No vitreous was lost. All the instruments used were taken directly from a cup of boiling water, and before the operation the lids, ball, and conjunctival sac were carefully cleansed with a 1 to 4,000 corrosive-sublimate solution. When the operation was completed everything looked satisfactory. A double compress bandage was applied, and the patient walked to her bed in the next room, a distance of not more than twenty feet. At the hospital our patients always walk from the operating-table to their beds, whether on the same floor or on one above. I am not able to persuade myself that this walk had anything to do with the consecutive hemorrhage. Two hours later she was resting comfortably. When I visited her the following day she told me that she had been awakened during the night by a severe pain in the eye. As nearly as she could fix it, the time of this pain must have been seven or eight hours after the operation. On removing the bandage I found the cotton and gauze had been soaked with blood. There was a clot between the lids, and, on washing this away, another was found between the lips of the corneal wound. The patient was still suffering, and asked that leeches might be applied to her right temple. This was done, with excellent results, as far as the pain was concerned. A little oozing from the eye continued for a day or two, when it ceased. A mass of intra-ocular tissue filled up the corneal section, the protrusion being noticeable beneath the upper lid. The black pigment of the uveal tract could be distinctly seen. A firm compress bandage has been kept on since the operation. She has not suffered much—indeed has been quite comfortable. The protrusion from the corneal wound has nearly disappeared, and the ball has shrunken. The cornea is clear, there is some anterior chamber, and the outlines of the pupil can be followed. The pupil is partially closed by what looks like an opaque capsule. There is light perception, and she claims to be able to sometimes see objects in the room. I hope such is the case, but I doubt it.

During the twelve years' existence of the Presbyterian Eye and Ear Hospital (up to January, 1889) there have occurred at the institution two cases of intra-ocular hemorrhage after operations upon the iris or lens. One followed cataract extraction, the other an iridectomy for the relief of glaucoma. During these twelve years there were 910 cataract extractions and 135 iridectomies for glaucoma alone. Professor Chisolm operated upon both of these cases, and has kindly furnished me the following notes:

A man, fifty years of age, was treated at the hospital ten years ago. He had double corneal clouding from old ulceration. There was no anterior synechia or staphyloma, and not a suspicion of secondary glaucoma. In each eye was a mature cataract. He was told that the visual results could not be great on account of the corneal opacities, but that some benefit might ensue from the removal of the cataract. The operation was performed under the anæsthetic influence of chloroform. During the entire operation there was neither vomiting nor muscular movement. Iridectomy was done, and the operation was in every way normal. The lids were closed, and a piece of linen put over them. Before applying the cotton pad and bandage it was noticed that the linen was more saturated with liquid than was usually the case. Lifting the linen and opening the lids it was observed that the hyaloid membrane had burst, that the liquid vitreous had gushed out, and was about being followed by hemorrhage, which was soon established—the blood pouring through the corneal wound. The patient was still chloroformed and perfectly passive. Dr. Chisolm adds: "Knowing that the eye was lost, and panophthalmitis most likely to ensue, and having prepared the patient in advance for possible failure, I felt my best service to him was to save him the many days of suffering, great swelling, and tedious convalescence which belong to panophthalmitis. I therefore proceeded at once to enucleate the hemorrhagic eye."

The other case was that of a girl, aged twenty, who was afflicted with double chronic glaucoma. The right eye had less sight than the left. She desired an operation upon one eye, and the right was selected. Chloroform was administered, and during the entire operation the patient was perfectly quiet. There was no vomiting. The operation was smooth. Before the bandage was applied hemorrhage ensued. The lens was displaced, and the eyeball filled with blood which escaped from the wound. She was allowed to recover from the chloroform and the condition explained. Two days later the ball became painful and the conjunctiva chemotic—the early symptoms of panophthalmitis. The eye was then enucleated. Several days after this the other eye was iridectomized, the operation preserving sight, which is still good. Dr. Chisolm's record does not state that there were no spots of apoplectic retinitis in this eye, but from this fact, as well as from his clear remembrance of the case, he is sure the retina was not diseased. The patient was under his care eight years ago.

When I read this paper before the Clinical Society of Maryland, my friend Dr. E. H. Kuykendall, then Resident Physician at the Presbyterian Eye and Ear Hospital, narrated a case which occurred last spring at the hospital. It is so instructive that I have asked the doctor to give me notes of it, which he does as follows: Mrs. K——, sixty years of age, had been operated upon for cataract in the right eye, some four years past, by a prominent specialist in this city not connected with the above hospital. "From the moment of the operation she suffered dreadfully for several days, when the eye was removed." This was the history she gave. Examination revealed a mature "black" cataract in the left eye. She desired to have this removed. There was good light perception and normal tension. The lens was removed by Dr. Chisolm, with iridectomy, under cocaine. The operation was without complications. After the application of the bandage the patient was led to her bed in the next room, and told to keep quiet. This was between three and four in the afternoon. She was comfortable when the doctor made his rounds in the evening, and stated the next day that she had slept well during the night. Shortly before eight in the morning—*sixteen hours after the operation*—the nurse heard her cry out that "the eye had burst." The doctor saw her within a half hour. She said to him: "Doctor, my sight is gone. The eye has burst, just as the other one did." On removing the bandage a large clot was found between the lids, and filling the corneal wound. Panophthalmitis did not ensue, and the patient left the hospital two weeks later, hopelessly blind.

The only other case I have known to occur in this city was narrated at this meeting of the Clinical Society by Dr. A. Friedenwald. In this case the hemorrhage occurred almost immediately after the extraction of an uncomplicated cataract.

Now and then a case appears in the journals, one in the September number of the *Archives of Ophthalmology*, showing that this hemorrhage may endanger life. The reporter is Dr. Baldwin, of Montgomery, Ala. The patient was a healthy colored woman, sixty-three years of age. The flow of blood commenced while she was still on the operating-table, and soon became so excessive as to cause serious exhaustion. The hemorrhage was only checked after eight hours' use of iced compresses. Panophthalmitis speedily followed.

So far as I know our text-books either neglect this matter altogether, or allude to it so casually in the discussion of another subject as to attract but little attention. Soelberg Wells is more direct than other authors. Discussing secondary glaucoma, he says: "Glaucoma may also complicate diseases which stand in no causal relation to it. Thus it may supervene upon senile cataract. . . . The cataract should never be

removed at the same time that the iridectomy is made for the relief of the glaucoma, for in case any vitreous humor should be lost during the extraction of the lens it might very easily give rise to severe intra-ocular hemorrhage." In discussing cataracts he speaks of occasional hemorrhage into the vitreous after extraction. The eye is usually diseased if this accident occurs.

Two interesting and instructive articles upon the subject are those of Dr. A. Fage, interne of Badal's Clinic, at Bordeaux, and of Dr. Warlomont, of Brabant. The former is in the *Archives d'Ophthalmologie* for July and August, 1889, and the latter in the *Annales d'Oculistique* for July, 1883. Fage reports a case occurring in Badal's practice. The cataract was of the uncomplicated senile variety, and the extraction was not marked by anything abnormal. The patient became conscious of the eye being wet shortly after his return to bed. Four hours later the bandage was soaked through with blood. Badal enucleated the eye ten days later, on account of panophthalmitis. Fage describes the following varieties of hemorrhage during and after cataract extraction. 1. The filling of the anterior chamber with blood from the conjunctival vessels—a perfectly harmless and common occurrence. If iridectomy is done, obstinate hemorrhage may take place from the iritic blood-vessels, "when, for any reason, the divided vessels do not retract after their section." Among the causes of this he mentions chronic iritis, atheroma, and rheumatism. Neither of these hemorrhages is at all serious. 2. Bleeding may also take place from the degenerated iritic vessels on account of some jar given the eye or movement of the patient in bed. 3. The dangerous class of intra ocular hemorrhages are those in which the blood comes from the posterior blood-vessels. These are specially apt to occur after the removal of glaucomatous cataracts. "This hemorrhage," he says, "finds its explanation in the alteration of the vessels of the eye existing at this time, and in the sudden diminution of tension which follows the opening of the eye-shell; but we see also this accident occurring immediately after the delivery of the lens, with persons whose eyes seem to present nothing abnormal." Fage examined the eye enucleated by Badal. He found that the blood had forcibly separated the sclerotic and choroid, and that the starting-point of the hemorrhage had been in the choroid. Microscopic examination showed the choroidal vessels to be perfectly healthy, except that they were gorged with blood. There was no degeneration of any kind in the walls.

Warlomont's experience was a peculiarly sad one. In April, 1883, he removed an uncomplicated cataract from the eye of a healthy woman, making a small inferior incision with iridectomy.

The operation was easily performed. Not a particle of vitreous was lost. On her way to bed, on the floor below the operating-room, the patient was attacked with nausea and vomited; "at the same time," he says, "she felt the operated eye become wet, and the nurse saw that pieces of the dressing were stained with blood, which very soon ran in a stream down the cheek." Warlomont enucleated the eye at once. The eye was examined by Dr. Van Duyse, of Ghent. He reported that in all probability the hemorrhage had started from the interstitial vessels of the choroid, and had become retrochoroidal, especially in the upper and anterior portion of the globe; that the membranes had been pushed downward and forward toward the corneal wound; that in this way the mass of blood between the choroid and sclerotic had caused the expulsion of the entire vitreous body, with the detached retina and choroid. The ciliary bodies and iris shared the same fate, the intra-ocular tissues being thus pushed into the corneal flap. Histologically the choroidal and retinal vessels showed nothing abnormal, except that they were greatly gorged with blood. He adds: "Nothing, then, in the histological examination furnishes an appreciable contra-indication to an operation by extraction upon the second eye." Warlomont thought over the case in the light of this report. He seems to have concluded that the mechanical effects of the vomiting or jar in walking down-stairs might have had a great deal to do with the hemorrhage. Taking all possible precautions against these influences, he decided that an operation upon the other eye was justifiable.

On July 16th Lebrun extracted the cataract by his median corneal incision, this being chosen so as not to invade any vascular part of the eye. No iridectomy was performed. After the natural and easy delivery of the lens, the vitreous was seen to bulge up against the cornea, but there was no prolapse. The patient was carefully moved to her bed, placed at the side of the operating-table, and did not leave the horizontal position. Previous to this a compress bandage had been applied. Within a few minutes intra-ocular hemorrhage ensued, destroying the eye.

There are three important factors in the treatment of such cases. 1. Is prophylaxis possible? Is there any way of diagnosticating, before operation, the existence of danger of intra-ocular hemorrhage? Warlomont thinks we should suspect eyes that are "hard, over the sclerotic of which run tortuous veins" ("glaucomatous" eyes), . . . "whose iris adheres at certain points to the capsule, and which often inclose a fluid vitreous body and an altered choroid." He does not say, Do not operate upon such eyes, but in doing so to use compression and to avoid the least possible shock. Some authors think posterior staphyloma is a condition to be mistrusted. Dr. Chisolm's case would indicate that a history of old corneal ulceration is to be regarded with suspicion. Increased tension, then, and fluid vitreous seem to be danger signals. Unfortunately our means of diagnosticating the latter condition are not great when the pupil is clear; when it is shut up by a cataract they practically amount to nothing. Prophylaxis, then, is an impossibility, unless one regards every case as suspicious and treats it accordingly. Even then, when he meets the eye with a hemorrhagic tendency he will probably lose it, as did Lebrun in the case cited. Warlomont concludes that "with nothing to indicate it, certain eyes cannot undergo the removal of the crystalline system without the place becoming vacant by this removal being immediately occupied by the vitreous body, pushed forward, occasionally followed, by the sclerotic, this resulting in the rupture of perfectly healthy vessels."

A second question in the treatment is, What to do with the hemorrhagic eye? In most instances panophthalmitis ensues, and a speedy removal will save the patient much suffering. When it is certain that the eye has been destroyed, enucleation should be done at once. Such certainty was absolute, for instance, in the two cases I have reported from Dr. Chisolm's practice. The lens and vitreous were seen to leave the globe, followed by blood. Nothing could possibly be gained by delay. But the loss is not always so sure. Fage gives three remarkable observations, published by Dr. Armagnac in the *Revue clinique d'Oculistique du Sud-Ouest*, 1884. I have not been able to get Armagnac's article, but Fage quotes him as follows: "Not only could the eye be saved, but vision was satisfactorily restored, equal to one-fourth in the first case, in the second allowing the patient to devote himself to farm labor, and in the third, on the authority of Dr. Magné, permitting the patient to read with a glass of 15 diopters" (convex $2\frac{7}{9}$) "No. 1 of the test-types." It is hard to see how such restoration could take place if the blood came from the choroidal vessels. If the hemorrhage occurred from the anterior vessels of the eye, it might be possible, if the vitreous chamber was not filled with blood. In view of the uncertainty attending the diagnosis when the hemorrhage occurs, not on the operating-table, but after the patient has gone to bed, Fage advises, on the authority of Badal, to postpone enucleation until "it has been demonstrated that the eye is positively lost;" in other words, until the early symptoms of panophthalmitis appear.

A third, and immensely important, question is this: If an eye has been lost by intra-ocular hemorrhage after the removal of a cataract, and one exists in the fellow-eye, what course of treatment should be followed? The case of Warlomont and Lebrun, and the one furnished me by Dr. Kuykendall, are very significant. They show that, whatever the underlying cause of this hemorrhage, it almost certainly exists in both eyes. How can the cataract be removed with the least possible danger? Fage quotes Abadie[1] as proposing "continuous compression of the carotid for twenty-four hours." In case this is impracticable, he himself suggests "previous injections of ergotine in the temple, the use of some other method than extraction by flap, the tight application of a bandage, absolute immobility of the patient," etc.

Warlomont weighed his own large experience against the following dictum of Liebreich: "One must not operate upon the second eye by extraction when this accident has occurred in operating upon the first." ("Il faut se garder d'opérer le second œil par extraction lorsque cet accident est survenu en opérant le premier.") Substitutes for extraction, such as needling or reclination, give very uncertain and transient results in old persons. His patient had only the one eye, and he decided not "to deprive her of the benefits attendant upon the model operation." From his unfortunate experience he decides that "it is not right to set aside the experience of others," and . . . "to consider the second eye, when the first has been lost by hemorrhage, as justifying only operation with the needle."

May 26, 1890.—My patient, Miss T——, has occasionally suffered from pain since the operation. The eye is not perceptibly smaller. The cornear is clear, but the section is filled with a mass of tissue. The iris is pulled up into the scar of the section, completely closing the pupil. The anterior chamber is obliterated. There is good light perception.

Clinical Department.

COFFEE IN COCAINE-POISONING.

By S. MITCHELL, M.D.,
HORNELLSVILLE, N. Y.

The many and varied symptoms arising from cocaine-poisoning are so distressing to the patient and trying to the physician, that the ingenuity of the latter is often taxed to the utmost in striving to relieve the same.

The extreme pallor, muscular weakness, and feeble and irregular pulse, seem to demand the most active stimulation, and yet, all who have been called upon to relieve these cases and have turned, almost instinctively, to such remedies as ammonia, brandy, and digitalis have, I doubt not, in cases where the symptoms are very pronounced, been sorely disappointed.

In the very mild cases these remedies have afforded almost immediate relief. But their action is singularly inefficient where the slight dizziness, faintness, and trembling are speedily followed by great pain in the precordial region, a weak and rapid pulse, sighing respiration, borborygmus, and belching of gas from the stomach, stiffness of all the muscles, and finally, paralysis of nearly the whole body except the brain, and this remains preternaturally active.

These severe and protracted symptoms I witnessed recently in one of my patients, and since this occurrence, when using cocaine hypodermically, a vision arises before me of this patient as she appeared with the whole body apparently paralyzed, except her tongue. This unruly member continually uttering words of reproach to me for the helpless and hopeless condition in which I had placed all the other members, gave me a sensation that I have no desire to experience again.

[1] Société Française d'Ophthalmologie, 1884.

It was in this case that I first employed coffee as an antidote for cocaine-poisoning. After using ammonia, brandy, and digitalis both hypodermically and orally, also heat and general faradization without any apparent effect, unless it was to stimulate my patient's tongue to utter such cheerful and encouraging remarks as "Oh, doctor I am paralyzed! I am dying! Oh, why did I come to you?" and while cudgeling my brain to think of something that might be more effective than the remedies already employed, my wife came to my assistance with the suggestion to try coffee. It was given clear, a large cupful being administered inside of two minutes.

The effect was all that could be desired. The pulse very soon improved, the pain and sense of oppression about the heart were relieved; in fact, all the disagreeable symptoms, except the stiffness of the muscles, passed away very rapidly, greatly to the relief of patient and physician.

I have employed it since in a great many cases when the toxic symptoms of cocaine began to show themselves, and always with perfectly satisfactory results. I have also employed it to relieve the extreme nausea with heart-failure that sometimes follows the administration of ether, and always with better results than with any other remedy.

I use it as ordinarily prepared for the table, with the exception that I pay no attention to the temperature. It is just as effective when used cold as hot.

It has been suggested to me to try caffein hypodermically, as likely to be more effective in these cases than the infusion. But I do not think it would answer at all, as caffein is a sedative, and its therapeutic effect seems to be scarcely at all identical with the pleasant and invigorating stimulation of the infusion that makes it so deservedly popular, which properties can hardly be attributed to the alkaloid caffein.

AN IMPROVEMENT IN THE PUS BASIN.

Dr. John E. Walsh, of Washington, D. C., writes: "It has always occurred to me that the ordinary pus basin is a very crude affair. Being so shallow and not containing much fluid, it has to be emptied or changed very often, and in doing this it is almost impossible not to spill some of its contents on the bed or clothing of the patient. I have arranged one which, I think, obviates this difficulty by emptying itself without being moved from its position. It is made by simply punching a hole in the bottom of the ordinary basin, of sufficient size, and fitting in it a hard rubber nozzle over the end of which is drawn a piece of flexible rubber tube long enough to drain into some larger receptacle.

"I have fitted one this way, and it has been used to great advantage in the Washington Asylum Hospital, of this city, especially in opening and washing out abscess of the breast, at the bedside. My excuse for occupying your valuable space with this description is, that I thought it might be of benefit to your many readers."

The Duty on Cod-liver Oil is now $2.25 per barrel. The McKinley Tariff Bill proposes to raise this to $5.00 per barrel. A large number of importing and manufacturing druggists have signed a protest against the proposed increase and ask that the duty be taken off altogether. Cod-liver oil cannot, it is stated, be manufactured in this country in sufficient amount to supply the demand because there are not enough cod.

Ingersollism and Quackery.—The Boston Ingersoll Secular Society recently discussed the proposed Massachusetts medical practice act, and its sentiments were expressed as follows by one of its members: "I admire a quack, he represents progress, and discovery, and new ideas. Without the quack we can have no reform. I do not believe that this bill, aiming at a monopoly of the worst type, can ever become a law."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 31, 1890.

PRIVILEGED TESTIMONY AND CENSUS TAKING.

IT is well known that on June 2d the stupendous undertaking of numbering the inhabitants of the United States will commence. Great excitement has been caused among the laity by the addition to the usual questions asked in census taking of those relating to physical conditions. Besides the name, age, sex, color, and occupation, the census enumerator is to ascertain whether the person is insane, feeble-minded or idiotic, blind, deaf, dumb, crippled, maimed, lame, deformed, or suffering from acute or chronic disease. Of course in hospitals and institutions there will be no trouble in obtaining statistics relating to impairment of mental and physical conditions. The annual reports which such institutions make are at the service of the census taker as they are at the service of the public at large; but the superintendent of the census realizes how very difficult will be the undertaking of collecting statistics of such conditions in private life. Dr. J. S. Billings, who is in charge of the vital statistics, has therefore issued a circular to all of the physicians in the United States asking them to fill out lists of names in the forms which accompany the circular, so that they can be compared with the lists furnished by the enumerators. He desires to know the insanity, form of insanity; if blind, the nature and cause of blindness; the nature of deformity, disease, or injury from which the person is suffering.

The result of such an inquiry if obtainable and *accurate* would of course be most interesting; but here is the rub. All statisticians know that it is impossible to obtain an accurate report of physical conditions among the population of the United States, and that any scientific work or deductions based on such data are of little value. The public have a right to know of contagious diseases; they affect the health of the community and the concealment of their presence is a crime against it. Nevertheless there are many cases of diphtheria, scarlet fever, and innumerable cases of measles which are never reported. Even births and deaths are not accurately recorded, although the necessity of obtaining burial permits makes the records of deaths the most accurate probably of all the vital statistics. This refers, of course, to the number of deaths, but as to causes of deaths, the information, except on broad generalizations, is of very little use to the investigators of the many questions which arise relative to the prevalence of disease.

As the returns of the census ordinarily give the number of people who are pursuing occupations, and the kinds of occupation, and include also information in regard to the various industries, the unemployed, either through idleness or disease, can be ascertained in a negative way.

It seems a great waste of work in printing, sending out the circulars, and assimilating the facts so ascertained. The amount of money expended on clerks who do the writing and tabulating is very great, and after all this is done, imperfectly as it must be, what advancement in science will be gained? Or suppose the able special agent of vital statistics should be so fortunate as to secure a perfect co-operation of the medical profession of the United States, and each physician should conscientiously fill out the blanks sent to him, of what great advantage would it be, over and above that which can be obtained from institutions, hospitals, factories, workshops, and schools, where, without intruding upon private life, the data can be accurately ascertained?

Finally, has the physician a right thus to hand over to the government facts which his patient and his friends are unwilling to make known? Can a physician feel justified in thus violating the confidence reposed in him by his patients? The request is worded as follows:

"Please fill out these lists for the persons of your acquaintance, or in whose families you practice (who have the physical infirmities we have already mentioned). It is essential to have the name, the sex, the color, and the approximate age, the place of residence, and also the name of the householder of whose family the person is a member, in order to identify the name in the enumerators' lists."

It certainly seems to us that it would be a matter of grave impropriety for the medical profession to lend itself to work of such a nature. On purely ethical grounds there is no possible justification for the request.

We venture to predict that, as far as the medical profession is concerned, all the labor of compiling and issuing of this remarkable circular will be lost. Each physician to whom it has been sent will have but one opinion of the propriety of the measure, and will not respond accordingly. His obligations regarding compliance with the request are entirely on the other side, and it is easy to foretell the result—the physicians cannot and will not respond.

PULSATION IN THE UVULA AS A SIGN OF AORTIC INSUFFICIENCY.

IN ordinary conditions of health there is no pulsation in the soft palate, or uvula, that is visible on simple inspection, so that when such a pulse is present it may, as a nearly constant rule, be taken as a sign of disease. In a recent memoir (*Charité Annalen*, xiv., 1889), Dr. F. Müller, of Berlin, has reported a case in which he observed rhythmical pulsations of the soft palate. The case was one of aortic insufficiency. A slight attack of pharyngitis led to an inspection of the throat, when it was seen that with each carotid pulsation the tonsils and pillars of the fauces moved slightly toward the median line, while the soft palate and uvula were somewhat lowered, so that there was a rhythmical contraction of the

faucial opening at the same time that there was an increase in the redness of the mucous membrane. Inspection of the throat after the inflammation had subsided showed the pulsations still present, though somewhat less pronounced. His attention having been thus called to this peculiar condition, Dr. Müller searched for it in six other cases of aortic insufficiency, and found it four times in a total of seven cases.

In an article in the *Gazette Hebdomadaire de Médecine et de Chirurgie*, March 15, 1890, Dr. P. Merklen quotes these cases and refers to an observation of his own. The patient was a young man who had a double mitral and aortic lesion, with marked hypertrophy of the auricle and left ventricle. The subungual capillary pulse was distinct, and in addition the palatal pulse was very evident on inspection. This was more particularly marked in the uvula, which could be seen to swell synchronously with the carotid and radial pulses.

Although, as Dr. Merklen remarks, this sign can have no great clinical value as an aid to diagnosis, it would, nevertheless, be interesting to learn with what constancy it is present in cases of aortic insufficiency, and whether the pulsation is ever visible in any other conditions. Müller never observed it in any other cases than those of aortic insufficiency, and Merklen has also examined many patients without this condition, but failed to find any pulsation. It is certainly not present in all cases of aortic insufficiency, for Müller looked for it in four such cases, but could not detect it. The palatal movements are not caused by transmission of the carotid beat, but are probably produced in the same way as the capillary pulse seen under the finger-nails in cases with similar cardiac lesions.

NITROUS OXIDE ANÆSTHESIA.

It is very generally held that the loss of consciousness resulting from the inhalation of nitrous oxide is due wholly to asphyxia. This opinion is the result of a close study of the physiological action of the agent. It has recently been asserted, however, by Krishaber, that the effects upon the circulation of mechanical asphyxia are widely different from those produced by nitrous oxide inhalation. As this assertion seemed to be contradictory to what had previously been affirmed by Jolyet, Blanche, and others, Drs. H. C. Wood and David Cerna were led to make a thorough investigation of the subject, the results of which were embodied in a paper read by Dr. Wood before the National Academy of Medicine.

There were three points to be noted particularly in this investigation, viz., 1, The time required from the beginning of inhalation to the development of complete anæsthesia; 2, the effect of the agent upon the rate and character of the pulse; and, 3, its influence upon the blood-pressure.

The test used to determine the presence of complete anæsthesia was the abolition of the conjunctival reflex. The length of time required for this effect to be produced varied in the different experiments from 51 seconds to 3 minutes and 50 seconds, the average period being 2 minutes and 8 seconds. The pulse-rate was found to be very decidedly slowed, while the arterial wave was enormously increased in size. This slow, huge pulse was absent when the pneumogastric nerves had been previously divided, so that it was evidently due to stimulation of the inhibitory cardiac apparatus. The effect of the inhalation upon the blood-pressure varied somewhat in the different experiments. In most instances there was an extraordinary rise in the arterial pressure, occurring sometimes at once and at other times not until the animal was completely anæsthetized. In all cases, if the inhalation were continued, the blood-pressure began to fall and finally reached the zero line. This did not occur, however, until long after the complete cessation of respiration, and the animal died from asphyxia and not from cardiac failure. Further experiments showed that this rise of blood-pressure was due to vaso-motor spasm, accompanied by a very pronounced increase in the force of the heart's beat. The secondary fall of arterial pressure was found to be dependent upon vaso-motor paralysis. The addition of ten per cent. of oxygen (one-half the proportion existing in atmospheric air) was found sufficient to prevent any anæsthetic action, and also suspended the action of the gas in raising blood-pressure, but did not destroy its power of reducing the pulse-rate, this seeming to show that the anæsthetic and vaso-motor influences of nitrous oxide are in some way apart and separate from its action upon the pulse. Yet the latter action would seem to be rather indirect than direct, as much the same effect was produced by inhalations of pure nitrogen.

Dr. Wood concludes from these experiments that both nitrous oxide and nitrogen act by shutting off oxygen. The blood-changes produced by inhalations of either gas resemble those caused by mechanical asphyxia, though they are not identical. The rise of pressure is usually much greater in mechanical asphyxia than during the inhalation of either of these gases; but the amount and duration of the circulatory disturbance vary greatly even when the trachea is hermetically sealed. It would, *a priori*, be expected that there would be differences in this respect, for in mechanical asphyxia there is an accumulation of carbonic acid in the blood, but in that caused by the inhalation of an inert gas the carbonic acid formation is checked while its excretion is unhindered, the result being that it is reduced in amount. But any differences that may exist are not a sufficient foundation for an argument that nitrous oxide acts as a direct anæsthetic, that is, that it produces anæsthesia by virtue of any inherent property which it alone possesses, and which is not common to all non-irritant inert gases.

THE ACTION OF COFFEE UPON THE ORGANISM.

Considerable attention has been paid recently to the subject of the physiological action and nutritive value of coffee. In a long contribution made by Professor Gee recently to the Académie de Médecine, he discusses the view, which is thought to be the prevailing one, viz., that coffee or caffein lessens nitrogenous waste and is an *aliment d'epargne*, or a food that acts by decreasing tissue waste. On the contrary, he asserts that its use increases nitrogenous metabolism and the excretion of urea. Its utility depends, therefore, upon its stimulant effect upon nervous action and metabolic processes.

While M. Gee is, in general, correct in his view, the

statements which he makes are not new, and are fully in accord with those reached by others long ago.

The experiments of Hoppe, Rabiteau, Roux, and others, which showed apparently that coffee causes a slight decrease in the excretion of urea, have not been accepted as of scientific value; while Voit's exact experiments upon dogs showed that there was an increase in this product. By the use of coffee, says Rossbach, tissue metamorphosis is slightly increased, and absorbed food is used rather more quickly; but it is not an *aliment d'épargne*, nor does it act as a food in an appreciable degree.

Dr. Edward T. Reichert, in a recent article (*New York Medical Journal*, April 26, 1890) on the action of caffeine, states that the conflicting results regarding the effects of coffee upon the excretion of urea and CO_2 are explained by the fact that such experiments are of no value in determining the influence of a drug upon tissue change. The only certain method of solving this question is by calorimetric measurement. Dr. Reichert reports three series of experiments upon dogs, made in accordance with this view. His results show that caffeine increases heat-production and heat-dissipation, and therefore destructive tissue metamorphosis. He concludes that the virtues of tea and coffee are entirely dependent upon the exhilarant effect each has upon the mental functions and its excitation of the higher nervous tissues. It does not replace food or increase the power for work without corresponding tissue destruction.

SUGAR OF MILK AND THE TARIFF.

The manufacture of sugar of milk may be regarded as a representative infant industry—from the material point of view. For this reason, perhaps, the McKinley Tariff Bill proposes to stimulate it by putting a duty of ten cents per pound upon the imported article. This has raised a strong protest on the part of numerous wholesale druggists, who assert that sugar of milk is used almost entirely for medicinal purposes, and in preparing foods for infants. Sugar of milk is now obtained chiefly from Switzerland. Attempts to make it in this country have for the most part failed, and it is said that the climatic conditions are not favorable here to manufacturing this sugar. Over a quarter of a million of pounds are imported annually, at a cost of about sixteen cents per pound.

THE BINDER.

To bind or not to bind the parturient female is a question with which the obstetrician still allows his mind to wrestle. At a recent meeting of the Obstetrical Society of London it was concluded in effect that the doctor had better do as the patient felt inclined. The matter ought not to be left in such a doubtful state. Kingdoms rise and fall, great nations disappear, cyclonic storms and volcanic fires change the face of nature, but babies continue to be born and the mother insists on having a binder, or knowing the reason why.

The Obstetrical Society of London should not trifle with topics of such eternal moment. For our part, we say do not bind. The alleged comfort secured is imaginary, the idea that the binder can restore the figure is unscientific and unphysiological, its supposed power in helping involution is purely hypothetical, and the whole conception of a binder is unnatural and abhorrent to common-sense.

The binder is a relic, not of barbarism, for barbarians are too sensible to bind, but of a half-enlightenment that is worse than ignorance. The physician who binds nowadays does it out of a weak complaisance to an imperious mother in-law or officious nurse. He should, out of respect to his art, rise above such trammels to his medical skill and his intellectual independence.

STANDARDIZE THE FLUID EXTRACTS.

There are about one hundred and forty-five fluid extracts in use by physicians. The doses of these range from one minim to two drachms, or, in other words, the strengths vary from 1 to 120.

Dr. E. R. Squibb shows, in the following graphic table, this range of variation:

1	Minim	to	3	Minims	—4	10	Minims	to	30	Minims	— 1
1	"	"	4	"	—2	½	Drachm	"	½	Drachm	—10

It is proposed to standardize fluid extracts so that they will be of nearly equivalent strength, or perhaps to have two series of preparations, but each of the same strength. In this way much confusion and danger from wrong dosage will be avoided, while an enormous burden upon the memory will be removed. We trust that, if practicable, this reform will be carried out, and that we can say of fluid extracts—

> One hundred and forty-five extracts of but a single strength.
> One hundred and forty-five drugs whose dose is one.

LASSAR'S TREATMENT FOR BALDNESS.

Baldness and phthisis pulmonalis are the despair of therapeutists, and anyone who suggests a new remedy for either is at once elevated from obscurity to world-wide notice. Our contemporary, the New York *Medical Journal*, gives a detailed account of the treatment for alopecia pityroides and alopecia areata, devised by the talented Secretary of the International Congress, Dr. Lassar. The treatment is as follows, and is to be repeated daily for six weeks or more: 1. The scalp should be lathered well with a strong tar soap for ten minutes. 2. This lather is to be removed with lukewarm water, followed by colder water in abundance; then the scalp is to be dried. 3. A solution of bichloride of mercury, 1 to 900, the menstruum being equal parts of water, glycerine, and cologne or alcohol, is to be rubbed on. 4. The scalp is then rubbed dry with a solution containing beta-naphthol, 1 part, and absolute alcohol, 200 parts. 5. The final step in the process is an anointing of the scalp with an unguent containing two parts of salicylic acid, three parts of tincture of benzoin, and 100 parts of neat's-foot oil.

News of the Week.

Examiner for the Blind.—The Commissioners of Charities and Correction have appointed Dr. Henry S. Oppenheimer "Examiner of the Blind," for their department. There are about six hundred applicants annually who need the doctor's certificate to the fact that they are blind, and they share *pro rata* the amount set aside from the Excise Fund for their benefit.

State Medical Societies.—The following State Medical Societies hold their annual meeting in June: Colorado, at Denver, June 17th; Dakota, at Sioux Falls, June 12th; Delaware, at Wilmington, June 10th; Maine, at Portland, June 10th; Massachusetts, at Boston, June 10th; Minnesota, at St. Paul, June 19th; New Hampshire, at Concord, June 16th; New Jersey, at Schooley's Mountain, June 10th; Ohio, at Columbus, June 3d; Rhode Island, at Providence, June 12th; Vermont, at Rutland, June 26th; Wisconsin, at Milwaukee, June 24th.

A Check to Christian Science.—Two "Christian Scientists" of Jamestown, N. Y., treated a patient who was suffering from cancer. She died, and a coroner's jury rendered the following verdict: "Mrs. Barrows came to her death from cancer of the breast on the 8th of May. We believe that contributory to this death was the culpable negligence of Mrs. M. J. Smith and Mrs. E. G. Lovejoy, who were advised of the nature of the fatal malady with which deceased was suffering, and failed to resort to or advise treatment by any of the methods known to medical science. We further believe that W. A. Barrows was also negligent of his duty in not securing medical treatment for his wife when there was reason for believing that she was in need of such treatment."

A New Hospital is to be built and maintained in Sioux City, Ia.

Tuberculosis and Surgical Instruments.—A soldier who had borrowed a bugle belonging to a musician who was suffering from tuberculosis became himself a victim to this fatal disease.

Professor Horatio C. Wood, M.D., of Philadelphia, has been chosen by the General Committee of the International Medical Congress to represent American medicine in the delivery of one of the addresses before that body. A well-deserved honor for the man and the country.

The Tariff and Beef Extracts.—It seems that the McKinley Tariff Bill has made "an insidious thrust" at the imported fluid extracts of beef. According to the *International Journal of Surgery*, the bill in question contains a clause which will in effect prohibit the importation of fluid extracts of beef. Is it only a coincidence that about this time Mr. Armour is putting a preparation on the market?

The Pasteur Institute.—During the month of April seven persons were treated, all of whom at this time are in perfect health. In three of the cases the dogs were proved by the results of inoculation to have had hydrophobia, and in another, a second person, bitten by the same dog, died with symptoms of hydrophobia.

The Late Dr. Howard P. Trask.—At a meeting of the Charity Hospital staff of 1889–90 the following preamble and resolutions were adopted:

Whereas, It has pleased Almighty God to remove from this earthly sphere our worthy companion and professional brother, Dr. Howard P. Trask, of Chicago, Ill. We, his sorrowing associates, deeply conscious of the loss we have sustained, wish formally to record our high appreciation of his character and example; be it therefore,

Resolved, That we, as a staff, hereby express our sincere grief for the untimely loss of our friend. A man of unusually impressive and dignified presence, with a manner of mingled firmness and gentleness, he commanded the respect and won the confidence of all with whom he came in contact. In obedience to the Almighty power that rules the destinies of men, that can build up or cast down, that can give or take away, we bow in humble submission about the bier of our departed fellow-member and professional brother.

Resolved, That our staff most respectfully tender to Dr. Trask's bereaved relatives this expression of their profound sympathy, and the acknowledgment that by his death we lose a most esteemed friend and co-laborer in our profession. Be it further

Resolved, That a copy of these resolutions be sent to the family of the deceased, and that they be furnished to the medical journals of this city and Chicago for publication.

Joseph R. Crofton,
Henry A. Higby.

An Aged Physician.—Dr. Enoch Fithian, of Greenwich, N. J., celebrated his ninety-eighth birthday on May 10th. A number of his friends from neighboring cities were present to congratulate him upon his continued good health and to wish him many future anniversaries.

A Surgical Hoax.—One of the serious morning papers of Paris recently published an article entitled "A New and Effectual Way of Getting Rid of One's Surplus Fat." The operators were said to be Drs. Demars and Marx, and the writer of the article, by way of further vouching for the accuracy of his statement, says he was present at the operation, and that the subject or patient was a medical student who was a sad sufferer from excess of adipose deposit, and who had tried all the usual systems and regimens recommended in such cases without the slightest effect on his abnormal weight. It appears that the abdominal conformation of this poor sufferer was of a somewhat unusual kind, for below the umbilicus was a fold of skin loaded with fat, which reached down over his thighs like an apron; and, as may be well imagined, this infirmity greatly impeded the patient in his movements. The operation, which was minutely described, consisted in removing this particular adiposus. There are no such doctors in Paris, however, and the whole thing turns out to be a clever hoax.

American Laryngological Association.—The Twelfth Annual Congress will be held in the Johns Hopkins University, Baltimore, May 29, 30, and 31, 1890.

A Census of Hallucinations.—Professor William James, of Harvard University, Cambridge, Mass., requests answers from everybody to the following question: "Have you ever, when completely awake, had a vivid impression of seeing or being touched by a living being or inanimate object, or of hearing a voice; which impression, so far as you could discover, was not due to any external physical cause?" The object of the inquiry is two-fold: 1st, to get a mass of facts about hallucinations which may serve as a basis for a scientific study of these phenomena, and, 2d, to ascertain approximately the proportion of persons who have had such experiences. Professor James was appointed by the International Congress of Experimental Psychology, held in Paris in the summer of 1889, to superintend this "census of hallucinations" in America, and he asks for the co-operation of all physicians who may be actively interested in the subject. It is clear that very many volunteer canvassers will be needed to secure success. Each census blank contains instructions to the collector, and places for twenty-five names; and special blanks for the "Yes" cases are furnished in addition. Professor James will supply these blanks to any one who will make application to him for them.

An Orthopedic Section in the Congress.—A committee, appointed by the Orthopedic Section of the New York Academy of Medicine, has petitioned the Secretary-General of the Berlin Medical Congress to establish a Section of Orthopedic Surgery at the Congress. In view of the fact that orthopedic surgery is now a well established specialty the committee believes that it should receive recognition as such, and requests all those who are interested in orthopedic surgery to write to Dr. Lassar, Secretary-General, Karlstrasse, 19, Berlin, N.W., requesting that such a section be established.

Dr. Louis F. Love has been appointed Chief of Clinic in Ophthalmology at St. Mary's Hospital, Philadelphia.

A Dispensary which Pays its Medical Staff.—The work of the Eastern Dispensary is increasing so largely that the Board of Trustees have found it necessary from time to time to increase the medical staff of this institution. After June 1st the combined time of service of the medical staff will amount to between fifty and sixty hours daily. All the physicians serving the dispensary are appointed after a competitive examination, and are paid at the rate of $200 a year for each hour of daily service. The success attending this plan has been equally gratifying to the staff and the trustees.

New York Cancer Hospital.—Dr. B. F. Curtis, Dr. Frank Hartley, and Dr. Paul Outerbridge have been appointed surgeons to the New York Cancer Hospital. Dr. Clement Cleveland and Dr. Henry C. Coe have been appointed gynecologists to the same hospital.

American Neurological Association.—The Sixteenth Annual Meeting of the Association will be held at Philadelphia, Pa., on Wednesday, Thursday, and Friday, June 4, 5, and 6, 1890, at the Hall of the College of Physicians, southeast corner of Thirteenth and Locust Streets.

Another Death from Electricity occurred in this city on the 17th inst. The victim, an Italian boot-black, received the alternating current of an arc light of about 1,500 volts.

Ohio State Medical Society.—The Forty-fifth annual meeting will be held at Columbus, O., June 4, 5, and 6, 1890.

The Episcope.—We referred to Professor Stricker's exhibition of his episcope at the recent Vienna meeting of the German Medical Congress. Fuller accounts (*The Lancet*) of this interesting and ingenious instrument are now given: It consists of a system of convex lenses and plane mirrors, by which, using electric light, the image of any opaque body can be projected on to a screen in its natural colors. To the members of the Congress at first large sections of a human brain were shown, and the assembly was much surprised by the clear appearance of the difference of the white and gray matter, which was apparent even to the occupants of the back benches of the auditorium. Then the open thorax of a living dog was shown, and one could follow the changes in color and movements which the heart was undergoing during the suffocation of the animal, all the branches of the coronary vessels, and the changes taking place in them, being clearly seen. Another interesting demonstration was that of the movements of the stomach and intestines of a dog whose abdominal cavity had been opened. The movements were much better perceived by the aid of the episcope than could be possible even by direct inspection.

The State of Connecticut granted the sum of $30,000 for a Homœopathic Hospital at New Haven on condition that a similar sum be raised by the incorporators. The amount has been raised and a site purchased.

The Mechanical Treatment of Erysipelas.—Wölfler has published eighteen additional cases of erysipelas treated by pressure of strongly adhesive plasters. After the plaster is applied the disease extends into the compressed parts of the skin, which swell considerably and remain swollen for several days, and then both the swelling and the fever diminish. He recommends that by way of precaution a second line should be compressed several centimetres distant from the first. The part must be carefully inspected once or twice daily in order to detect any loosening of the plaster. Occasionally the erysipelatous inflammation extends in diminished intensity for a short distance beyond the first line of plaster, but this does not last long.—*British Medical Journal.*

The "Lady Doctor" Question in Germany.—A petition was lately presented to the Medical Assembly of the Grand Duchy of Baden by the German Women's Association of Leipzig, praying that women might be admitted to study medicine. The Assembly passed a resolution declining to take any step in the matter, on the ground that women are unfit for the learned professions, and especially for that of medicine, and, moreover, that the latter is already overcrowded. Herr Arnsberger, the Ministerial Councillor representing the Government, said the question was not yet ripe for solution. He also pointed out that the matter was one for the decision of the Imperial authorities, not for that of the individual States. A similar petition has recently been presented by the same Association to the Weimar Landtag, in which the ladies ask to be admitted to the University of Jena, not only to study medicine, but with the view of qualifying for appointments as scientific teachers.—*British Medical Journal.*

The Royal Oculist.—The following item of medical news appears in the *Sun:* "The Royal Oculist, Duke Charles Theodore of Bavaria, has just concluded what this most useful and hard-working of princes terms a month's holiday at Meran in the Tyrol. As soon as his arrival became known afflicted peasants from all the valleys and mountains of the Austrian, Italian, and Swiss Tyrol flocked into Meran and were treated gratuitously by the Duke, who in the four weeks performed fifty-three operations for cataract and one hundred and seventeen minor operations."

The New York Academy of Medicine has transferred its building, No. 12 West Thirty-first Street, to the Mechanical Engineers' Library Association for $60,000, after having held it at $80,000 for some time. The purchasing society has given a mortgage for $33,000 on the property.

Transport of the Sick in Germany.—The Prussian railway authorities have set apart a few carriages for the conveyance of sick persons; they are fitted up with beds and everything necessary for the purpose. Such carriages are already kept ready for use at Altona, Cologne, Erfurt, Wiesbaden, Hanover, and Berlin.

A New Pharmacological Institute in Connection with the University of Bonn was formally opened on April 22d with an address from Professor Binz. The Professor has had the Order of the Red Eagle (Third Class) conferred on him in honor of the occasion.

Dr. Wales L. Cary, a well-known young physician, died May 17th, at his home in Brooklyn. He was born in Boston, Mass., in 1861, and was graduated from the Long Island College Hospital.

Medical Congress at Valencia.—A Medico-Pharmaceutical Congress will be held at Valencia, in Spain, in the latter part of May. It will be divided into four sections, as follows: 1, Medicine; 2, Surgery; 3, Public Medicine and Specialties; 4, Pharmacy and the auxiliary sciences.

A Useful Charity.—The Paris Municipal Council has voted the construction of an asylum for pregnant women of the poorer classes who by reason of their pregnancy are rendered for the time being incapable of following their avocations.

Obituary.

WILLIAM H. BYFORD, M.D.,

CHICAGO, ILL.

Dr. William H. Byford, one of the most prominent physicians of Chicago, died on May 21st, of heart disease. He was born at Eaton, Preble County, O., March 20, 1817, and was left an orphan at nine years of age. He was apprenticed to a tailor at the age of fourteen, but at twenty began the study of medicine, and in 1844 was graduated at the Ohio Medical College. In 1850 he became Professor of Anatomy in the Evansville Medical College, and in 1857 went to Chicago as Professor of Obstetrics in the Rush Medical College. He was appointed Professor of Obstetrics and Gynecology in the Chicago Woman's Medical College in 1862. He was the author of numerous contributions to general medical and gynecological science and of a standard treatise on diseases of women.

Reviews and Notices of Books.

Diseases of the Nose and Throat. By Franke H. Bosworth, A.M., M.D., Professor of Diseases of the Throat in the Bellevue Hospital Medical College, New York, etc. Vol. I.: Nose and Naso-pharynx, with four colored Plates and one hundred and eighty-two Wood-cuts. Pp. 651. William Wood & Co. 1889.

This is, as stated, the first of two large volumes on diseases of the parts named in the title-page, and they form an important member in the group of medical works issuing under the general title "Specialties in the Practice of Medicine."

The name of the author has been so prominently identified with laryngological interests, and his participation in their discussion in medical bodies is so active, that a more than passing glance must be given the work. Although undertaken originally as a second edition of his volume on the same topic in 1881, the advances made in the physiology of nasal respiration and in the diseases of the upper air-passages have made imperative a thorough rewriting of the whole volume.

The first section embraces diseases of the nose; the second, diseases of the naso-pharynx; while the third section is devoted to a brief and accurate description of the various operations of removal of growths, of resection of deep parts, and of correction of deformities of the regions named. This surgical section will have especial interest for the general surgeon, to whose hands the graver operations, involving the deep parts of the face, are more likely to be intrusted than to the strict specialist.

The few chapters devoted to examinations in laryngoscopy and rhinoscopy are well written and beautifully illustrated. Not only here, but throughout the work, the author justly refrains from emphasizing his own instruments and methods, leaving to the discriminating reader the exercise of a critical judgment in selection. Chapter VI., on the "Physiology of the Nose," is one of the most interesting in the volume. The author regards the respiratory and phonatory functions as perhaps even more important than that of olfaction, and premises his discussion of this topic with the statement that the normal functional activity of the nasal passages determines the integrity of the whole of the mucous membrane of the respiratory tract below. After alluding to Magendie's statement in 1829, that inspired air rapidly acquires the temperature of the body by passage over the mucous membranes of the air-passages, and by being charged with vapor derived from them, the writings of Dunglison in 1844, of Vierordt in 1845, of Grehaut in 1864, of Rosenthal in 1880, and of others, are introduced as corroborative of this belief; it is noticeable that Dalton, in 1876, and Foster make no mention of this fact. The author elaborated this idea in a paper in 1885, and reasserts the position then held, that the nasal mucous membrane must furnish the five thousand grains of water to the inspiratory currents of air, which physiologists assert are carried through the respiratory apparatus in the course of twenty-four hours. This function, the author claims, resides in the so-called erectile tissue of the turbinated bodies; the intricate and complex mechanism of these bodies and of the nasal passages lends anatomical weight to the argument. Aschenbrandt in 1886, and Kayser and Bloch in 1887, made extended experimental investigations with similar results as to the respiratory functions of the nose. The author's views are based on the results of extended clinical observations, and are worthy of the highest consideration.

In acute rhinitis the author relies on cocaine as the most definite and certain means of controlling venous turgescence; he uses a four per cent. solution, with morphia, in liquid cosmoline, by means of a spray. The most frequent cause of hypertrophic rhinitis lies in a deformity of the nasal septum, whose development is chiefly

mechanical; it is usually acquired in infancy while the child is creeping on the floor or is learning to walk, and is due to falls and blows, which may occasion a separation of the two plates of the septum. The development of such a deflection is slow, and may be unnoticed for years after the reception of the injury. The author is not disposed to regard the smoking of tobacco as an important factor in the etiology of catarrhal pharyngitis, and quotes the Cubans as inveterate smokers of cigarettes, and at the same time as unusually free from throat catarrhs.

The popular fear that offensive and odorous discharges result from an ordinary catarrh is combated with the statement that ulcerative and necrotic processes can only be met with in connection with syphilis, scrofula, and similar serious disturbances. In such patients the author finds the offensive odor is due to a dry and furred tongue, acquired by sleeping with the mouth open. The middle-ear deafness, often found in cases of hypertrophic rhinitis, the author does not believe is due to an extension of the catarrhal process into the Eustachian tube, by reason of the continuity of tissue, but that the nasal stenosis diminishes air-pressure in the vault of the pharynx with each inspiration; this acting through a long period of time produces the category of symptoms usually found with middle-ear disease. This mechanical theory of deafness will not be generally accepted in view of the well-known behavior of catarrhal processes in the middle and upper air-passages. The galvano-cautery has come largely into use since its introduction by Middledorpf and Voltolini, but the author prefers a chemical cautery, the best example of which he finds in chromic acid. He has an angular probe, or applicator, which is dipped in mucilage, and a few of the acicular crystals of chromic acid are thus taken up; the whole is then fused over a flame into a small bead; this is used as a caustic, the parts having first been cocainized, without endangering healthy tissue.

The general concensus of opinion among aural surgeons is that hypertrophic rhinitis is found in cases of chronic middle-ear catarrh in greater frequency than is atrophic rhinitis; while Wyss, of Geneva, found forty-seven instances of impaired hearing in sixty cases of atrophic rhinitis, Burnett, of Philadelphia, found atrophy of the nasal mucous membrane in fourteen and a half per cent. of cases of chronic middle-ear disease. Beverley Robinson, on the other hand, states that aural disease is found more frequently in atrophic than hypertrophic rhinitis; while Roosa and Buck allude to both forms of rhinitis indifferently as factors in the causation of middle-ear catarrh. The author emphasizes his belief that the integrity of the ear, as that of the bronchial tubes, depends on a healthy activity in the nasal passages.

The chapter on "Nasal Reflexes," covering thirteen pages, is all too short; its brevity serves to enhance interest in the author's belief in them. It must not be inferred, however, that the trigeminus is the only nerve that plays the *rôle* of a reflex medium, or that the eye is the only organ reflected upon, as a hasty perusal of this article might lead one to infer. Suffice it to note here that the subject of reflex and peripheral irritation will form one of the most prolific channels of neurological investigation of the future.

Dr. Bosworth is a firm believer in cocaine in a watery solution, but preferably mixed with fluid cosmoline, as a menstruum. His reliance upon its property of contracting the blood-vessels in epistaxis, hay fever, or vaso-motor rhinitis, and upon its contracting and anodyne properties in asthma or vaso-motor bronchitis, and in hypertrophic rhinitis, makes him place it in the front rank of medicinal agents; but to place in the hands of the patient a two per cent. solution of cocaine, and an atomizer to use at will in hypertrophic catarrh, or a four per cent. solution, as he recommends for hay fever—and to add that cocaine is by him regarded as one of the most harmless of drugs so far as any danger of addiction is concerned, its excessive use being objectionable only as is the excessive use of tea and coffee—to do this is to invite criticism as to dangerous methods of advice and as to unsafe liberties. No discreet oculist would dare trust patients with cocaine solutions stronger than one-half or one per cent., the latter representing about five grains to the ounce.

On page 252 "Himrod's Powder" is stated to consist of the leaves of lobelia, stramonium, ordinary tea, with nitrate of potash. This powder contains no lobelia; but besides the three others named, contains other ingredients.

The chapter on "Septal Deformities" is admirably written, and should be read with care. As is well seen, the author believes in their discreet and partial removal, preferring the nasal saw to all other instruments. He has never seen a case of ulceration, and his experience has been large.

So graphic is the symptom of the voice in nasal polypus or myoma, that the phrase describing it is introduced here as written. "It is a peculiar dead voice, and yet with something more of resonance than the dead voice of an adenoid—a dead voice, perhaps with a faint nasal tone in it." The cold-snare écraseur of Jarvis is preferred to all other methods of removal, as most efficient, least painful, and safest. For this purpose a twenty per cent. solution of cocaine is atomized upon the part; with most operators a four or eight per cent. solution is sufficient, pencilled and not atomized, thereby preventing any overflow of cocaine.

The author's conviction, that in cases of hypertrophy of the pharyngeal tonsil, or adenoid growths of the vault, complete removal should be achieved, will be concurred in by every operator in this region. These growths are pathological, and are fibromas, or fibro-myxomas. Fibro-elastic or fibro-connective-tissue formation is more prominent in the hyperplasia of the faucial than in that of the pharyngeal tonsil. Presence of the latter interferes with the high register of the voice, and all obstructions at the vault and in the nasal fossæ should be removed in order to the full volume and timbre and resonance of the head register. Singers first fail in this end of the musical scale, and are conscious of failure by the muffled tone and lack of the sounding-board function of the upper throat. The amount of aural catarrh and deafness concurrent with adenoid growths is remarkable. Urbantschitsch found deafness 130 times in 175 cases of these vegetations; Meyer, 72 times in 102 cases; Swinburne, 27 times in 42 cases; Bosworth, 28 times, 8 of which were of extreme deafness, in 75 cases; while Woakes states that not more than five per cent. of his cases escaped aural complications.

The wood-cuts and the colored plates illustrating the chapter on the "External Surgery of the Nose" are all that can be desired. In fact the whole work is admirably and fully illustrated, leaving the mind clear as to the descriptions of the author. The bibliography of the volume is very full, its index alone occupying eight pages. The well-known clinical character of the author's productions is fully exemplified in the present volume; and no one interested in this branch of surgical knowledge can lay it down without feeling the confidence which a master-hand and a competent teacher inspire. There is but little to criticise and condemn; and the medical profession is largely indebted to the author for his able manual.

A Medical Library for Chicago.—The librarian of the Newberry Library, which has an endowment fund of $2,000,000, announces that in the construction of the library building one section will be devoted exclusively to medicine. It is the intention to place in that department a library so complete as to meet, as far as possible, the wants of all who wish to consult medical authorities. There will be also kept constantly on file, as they are issued, the current numbers of all prominent medical journals published in this, and in foreign countries.

Society Reports.

American Medical Association.

FORTY-FIRST ANNUAL MEETING.

Held at Nashville, Tenn., May 20, 21, 22, and 23, 1890.

(Continued from page 607.)

SECTION ON PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

FIRST DAY, TUESDAY, MAY 20TH.

The Address of the Chairman.—DR. JOHN H. MUSSER, of Philadelphia, delivered the annual address, in which he spoke of the greater facilities in the treatment of disease which were now enjoyed by the physician. But while this advance was for the benefit of the patient it had nevertheless resulted in throwing more work upon the physician. The practice of medicine now demands the expenditure of more time in the examination of these secretions and excretions, bacteriological investigations, etc., and it is but right that the physician should be compensated accordingly—he should, in other words, charge more than he now does, for the fees are as a rule much too small. A practitioner cannot do justice to his patients if he is not himself in good physical condition, and as a means to keeping himself in good health he must not work too hard. Overwork can be prevented by the employment of an assistant. The public will have to become used to this, but it would soon do so if the practice were universally adopted. The physician should lighten his burdens also by employing all the modern labor-saving methods. If he writes much or records all his cases he should have a stenographer and type-writer, and he ought, if possible, to have a female nurse always in his office. By the use of the telephone and phonograph he can further economize his time and strength. The physician owes it to himself to do this.

A Good Investment for Surplus Earnings is in the payment for summer outings and the purchase of the labor-saving means before mentioned. By so doing we become better able to treat our patients in the most efficient manner. The speaker also called attention to the advantage of employing trained nurses in private practice, and he heartily favored the suggestion, made long ago by the elder Gross, of establishing training-schools everywhere, in small localities as well as large. He urged a closer study of old methods of treatment and spoke with small measure of approval of the modern search after therapeutic novelties, and the almost reckless experimentation with new remedies. A problem which confronted the physician in this country was the change in physical constitution resulting from the amalgamation of races and the altered relations of life arising in our modern world.

Filaria.—DR. DE SAUSSURE, of Charleston, S. C., then read a paper on the filaria sanguinis hominis, his conclusions being based upon the study of twenty-five cases. He showed some specimens of the parasite taken from a dog, and later exhibited a patient suffering from the disease. He believed that the habitat of the parasite was in the South, and that cases of the disease observed in the North had always been contracted in the South.

DR. LOVERING, of Ohio, called attention to the similarity in the symptoms caused by the presence of trichina and those due to filaria sanguinis hominis.

The Turkish Bath in the Treatment of Rheumatism.—Dr. C. H. SHEPARD, of Brooklyn, N. Y., read a paper entitled: "Rheumatism and its Treatment by the Turkish Bath." After a brief review of the numerous theories broached from time to time, as to the etiology and nature of rheumatism, and of the unsatisfactory results obtained by the ordinary methods of treatment, he spoke at some length of the value of heat and especially of the application of heat in the Turkish bath. Rheumatism is a constitutional disease and requires constitutional treatment. Of all remedies advanced for its cure, heat is the most simple and the surest. He had records of over three thousand cases treated by means of Turkish baths, and of these a cure had been obtained in ninety-five per cent. Heat externally applied was not debilitating. It caused profuse perspiration but the water so lost was readily replaced in the system, and the effect of such sweating was to eliminate a vast amount of excrementitious material, including micro-organisms.

The paper was discussed by Drs. Ulrich, Didama, and Bailey, who were not in agreement with the reader of the paper as to the advisability of subjecting a patient with acute articular rheumatism to treatment by means of repeated Turkish baths.

Calomel in Dysentery.—DR. J. W. DAVIS, of Smyrna, Tenn., then read a paper in which he advocated the employment of calomel in the treatment of some forms of dysentery.

The discussion which followed was participated in by Drs. Ulrich, Dawson, Didama, Sloan, Musser, Davis, and Woodhull.

SECOND DAY, WEDNESDAY, MAY 21ST.

Calomel as a Diuretic.—DR. GEORGE FACKLER, of Cincinnati, introduced this subject by first reviewing its literature. It was of recent date and limited to the observation of few experimenters. The author related three cases of heart disease attended by œdema in which calomel, administered in doses of about four grains three times daily, usually continued four days or longer, caused decided polyuria and disappearance of ascites and œdema. In most of these cases digitalis and other of the older diuretics had failed. In a fourth case, in which the cardiac trouble was far advanced, calomel also failed to act as a diuretic. The drug, when administered in this manner, caused slight, sometimes severe, salivation and stomatitis. It was desirable that the calomel be retained as long as possible, in order that it might be changed into an albuminate, in which form it produced its action. His conclusions were as follows: 1. Calomel, and, in all probability, other mercurial compounds, possess diuretic action. 2. If given in proper doses, the effect of calomel becomes evident from the second to the tenth day. Continuation of the treatment during diuresis will not alter or increase the effect. 3. Its action is most marked in dropsies due to heart disease. Its action in dropsies of hepatic origin is not to be relied upon. Pathological changes in the kidney prevent or abridge its action. 4. Small doses are of no avail. 5. The diuretic action, in all probability, is due to the irritating effect which mercury exercises during elimination upon the renal epithelium.

DR. CALDWELL, of Florida, had produced diuresis by bichloride of mercury, one-thirtieth of a grain or more three times daily, in combination with muriate of ammonia, and had not been troubled by salivation. By eliminating the ascites and œdema sleep was obtained and the appetite improved.

DR. DE SAUSSURE, of Charleston, in treating a case of filaria, had observed diuretic effects from bichloride of mercury, and a ten-grain dose of calomel had been observed in Charleston to produce a diuretic effect in certain cases of œdema due to heart disease, but the action was not so long continued as when administered in the manner described by the author.

The Continued Fevers of the South.—The discussion on this subject was opened by DR. W. W. JOHNSON, of Washington, in a paper read by the secretary. The subject might be subdivided into four heads. 1. To what extent does typical enteric fever prevail throughout the South? 2. To what class do the negative or atypical forms of fever belong? 3. Is continued malarial fever or malarial fever of remittent type generally prevalent?

4. Is enteric fever of the South modified by malarial affections, giving rise to what has been termed typho-malarial fever?

The author thought enteric fever was a rare disease in the South in the typical or intense form. There was probably a change going on in the form of enteric fever in the South which had lessened its typical character. It was becoming milder. Many cases of mild continued fever which had no well defined course or symptoms were cases of mild enteric fever, erroneously diagnosticated at times as malarial and intermittent fever. There was no good reason to believe there was such a disease as typho-malarial fever.

Typho-malarial Fever Does not Exist.—Dr. John P. Wall, of Tampa, Fla., held that there was no such disease as typho-malarial fever in the South. Typhoid fever existed there, but of late years it was of mild form, and continued on an average three weeks. He thought typhoid fever might develop independent of a previous case, for he had seen it freshly appear in towns or country places entirely isolated. He disbelieved in the germ theory in this particular disease. Impure air and conditions of the soil were the chief factors in its production. Change in soil, condition, and climate would largely account for the change in the type of the disease.

In Western Tennessee.—Dr. T. J. Hoppel limited his remarks to typhoid fever as it had existed many years in Western Tennessee. When he first began practice there the cases were typical; now the reverse was the rule—enteric fever usually ran an atypical course. The cases resembled in some degree malarial affections, but did not respond to quinine. The morning temperature was likely to be 102°F., afternoon 104 to 106°F. The kidneys and bowels were torpid, the skin sallow. The fever might be continued or remittent, in some cases its duration had been eight weeks. Toward its declination there was a cold stage in the morning during which the thermometer might register 96° or 97°F. He did not think there was a distinct affection which should be called typho-malarial fever.

Typhoid and Malarial Fever in the Same Patient.—Dr. J. C. Shepard divided Tennessee into three geographical areas, one of which constituted a large basin; a second table lands; a third mountainous regions (Cumberland), this being perhaps three thousand feet above the ocean level. He had found enteric fever prevalent in mild form in all these regions, malarial fever particularly in the basin, less in the table lands, absent in the mountains.

But there was a modified form, partaking partly of the malarial, partly of the typhoid character, the former element predominating in the basin, the latter in the elevated regions. If the cause of enteric fever was a germ, the disease was yet modified by climatic and hygienic conditions.

Typho-malarial Fever Does Exist.—Dr. George Dock, of Galveston, said that a combination of typhoid and malarial fever had been demonstrated. In Texas, however, they never spoke of typho-malarial fever, but they had a continued fever which was commonly spoken of as catarrhal, and the question had been discussed among them whether they had to deal with typhoid fever or a catarrhal fever. As to the latter, there had been no autopsies to show its pathology out of the many cases in which it was said to have been the cause of death. His own opinion was that such cases were usually enteric, though not running a typical course. In half a dozen cases he had verified this view by an autopsy, at which the essential lesions of typhoid were found in the intestines. Those who held to the separate nature of catarrhal fever adopted a different treatment, giving heroic doses of antipyrine, one hundred and fifteen grains three times a day.

Dr. Sears had been practising thirty-five years in Texas, and had there seldom seen typical typhoid fever. But he had treated a large number of cases of continued fever which he had no hesitation in pronouncing purely malarial. They had the mixed types of remittent, intermittent, and continued malarial fevers. These fevers, if continued sufficiently long, might take on the typhoid state, as might pneumonia and other affections, especially when badly managed, but it was not really typhoid. The patient should take quinine, and although he did not claim that this drug cured, it did prevent fatal consequences. The recovery might be abrupt or gradual.

Atypical Typhoid the Rule.—Dr. Van Enam, of Kansas City, said that if typhoid fever were recognized only when all the symptoms were present laid down in the books a correct diagnosis would seldom be made. Atypical cases were the rule. There was but one uniform sign, and that would not be recognized during life. He referred to the intestinal lesions. He thought there could no more be a typho-malarial fever than a scarlatinal measles. He had frequently found the morning temperature of typhoid fever 97° F. The disease, in his opinion, was self-limited, and the patients who had received large doses of quinine got well in spite of the drug instead of because of its beneficial action.

Dr. Sears, finding the last remark elicited by his statement that in Texas large doses of quinine were demanded, even two ounces in three weeks, said the belief was founded on clinical observation. Patients with the affection referred to by him recovered when they took quinine, and frequently died without.

Dr. Powell, of Tennessee, thought that in what had been recognized in his State as typho-malarial fever there was a mild type of typhoid fever.

The Shield with Two Sides.—A member said the discussion reminded him of the story of the shield with a golden and a silver side. There seemed to be in some cases both malarial and typhoid fever, and according to the side from which the subject was viewed by the respective disputants was the honor given to the typhoidal or malarial in diagnosis.

The Malignant Type in New Countries.—Dr. Wilson, of the State of Washington, said that so called typho-malarial fever of a malignant type existed in some parts of their State. He believed it was only malarial, was milder in older States, and required quinine. There might in this disease be a typhoid state, but not true typhoid fever.

The Specific Treatment of Typhoid Fever.—The next paper, with this title, was read by Dr. J. H. Van Enam, of Kansas City. Impressed with the failure or injurious consequences of other methods of treatment, except those claiming to be simply palliative, and accepting the germ theory in its etiology, the author looked for a really curative agent in something which would destroy the germs in the body of the patient. An alkaline medium was required in culture processes, the least acidity destroying the germs. On this hypothesis he gave half-drachm doses of dilute muriatic acid every three hours night and day, having first cleansed the alimentary tract by calomel, and allowing only sterilized food. In the six or more cases thus treated there had been no delirium, no sordes, diarrhœa was arrested, recovery had taken place within twenty days.

Has Progress been made in the Medicinal Treatment of Typhoid Fever.—Dr. T. J. Hoppel, of Trenton, Tenn., in this paper gave some of the sources of error in attributing beneficial or curative effects to remedies applied in typhoid fever. Yet the mortality from this disease had gradually been reduced, and this result he attributed in part to the abandonment of injurious measures, and in part to the discovery of beneficial ones. He did not deny that the Brandt method of using cold water possessed virtues, yet he thought it had been often applied, and beneficial results attributed to it in many conditions mistaken for typhoid fever; that it was cumbersome, and professed to accomplish results which could much better be secured by antipyrine, and other measures. If it had been shown that germs were the cause of typhoid fever specific remedies could act only in killing these. His

best results had been obtained from antifebrine for reduction of the temperature when it rose above 102° F., from carbolic acid or the phenic preparations, alone or combined with iodine or ammonia, to destroy the bacilli.

Carbolic acid had a tendency to cause constipation and lessen the fluidity of the blood, which should be counteracted.

The Treatment of Insomnia and Neuralgia by Butyl Chloral Hydrate.—Dr. Hobart A. Hare, of Philadelphia, offered, as an apology for reading this paper, the fact that butyl chloral hydrate had been little employed in neuralgia in this country, whereas in England Ringer and others had found it decidedly useful in certain cases of insomnia and neuralgia. In a case of neuralgia and insomnia due to middle-ear disease Dr. Hare had found it of decided benefit; five grains in pills every two hours were taken until thirty grains had been administered, after which there was total relief. It had relieved functional insomnia from unknown cause, but did not always respond in insomnia due to advanced systemic conditions. It was beneficial in insomnia due to heart disease, and did not depress the heart. It was especially useful in insomnia with head pain, particularly where branches of the trifacial were affected.

The Chairman was authorized to appoint a committee to take into consideration the continued fevers of the South, to report at the next meeting.

Auto-Intoxication in the Presence of an Excess of Nitrogenous Food.—Dr. Sawyer, of Cincinnati, reviewed in a paper recent investigations concerning the toxic elements found in the intestinal tract and urinary excretion, and then related the histories of five cases in which a series of symptoms were present corresponding closely to those described by the discoverers of the ptomaines and leucomaines present under certain conditions. Among the symptoms were headache, loss of ambition, disinclination to work, local or extensive œdema, diminished quantity of urine, usually with an increase of urea, no rise of temperature, pulse slightly quickened but not of high tension.

The patients were accustomed to take a considerable quantity of meat, and when restricted largely to a vegetable diet the urea diminished in quantity, the specific gravity of the urine was lowered, and the mental and other symptoms disappeared. His own observations had been solely clinical, no search having been made regarding the existence or nature of toxæmic elements.

Third Day, Thursday, May 22d.

Oxygen, its True Value as a Therapeutic Agent.—Dr. J. M. French, of Cincinnati, had employed this agent almost constantly the past three years. He employed O_2, or nascent oxygen. It should be both fresh and pure. As was well known, there were two other forms of oxygen—atmospheric and ozone. When pure it was tasteless and unirritating. He saw no reason for claiming for O_2 any very different action than the physiological one of atmospheric oxygen. It was a difference of degree rather than of kind. It penetrated the blood more readily, but if this was granted its applicability would be extensive.

The results obtained from it were sometimes almost instantaneous. Aside from the sensation in the head, it caused a change in hue of the mucous membranes of the cheeks, etc., of a blanched patient; although sudden, the effect was not always transient.

In incomplete oxidation, more or less marked, attending diphtheria, asthma, tumors, renal disease, inhalation of noxious vapors, etc., the treatment was often markedly beneficial. The constitutional effects of the treatment were best seen in chronic diseases, not less in the kidneys and other organs than in the lungs. Above all was it useful in diseases of the blood, particularly the anæmias. Thus far he had found it more widely useful than the electric battery, and like it it should be used only in properly selected cases.

The Local Treatment of Phthisis Pulmonalis.—Dr. E. L. Schurley, of Detroit, had found by experiments on guinea-pigs, etc., that medicated inhalation, administered in a small room, frequently and for some time, left a deposit of the drug in the finer bronchi; not so when the inhalations were in larger rooms in which the air could not be saturated. These facts corresponded with clinical experience in the case of man. Inhalations by ordinary means employed by patients at their homes were of little value except where the process was confined to the upper air-passages. He thought it unreasonable to expect benefit from air passing over a sponge containing a few drops of creosote. In brief, he thought the profession should discard the ordinary inefficient means of using medicated inhalations, when it was desired they should reach the air-vesicles, and confine the patient to a room in which the atmosphere was saturated, or seek some other efficient method.

Drs. Bateman, Powell, McIntosh, Bailey, and others, who discussed the paper, could relate little positive benefit from medicated inhalations in phthisis, yet most of them thought greater success would be obtained if the medicated agent could be made to penetrate the air-vesicles.

Dr. De Saussure said consumption was likely to solve the race problem in Charleston, for there the negroes were dying in large numbers from this disease.

Functional Albuminuria.—Dr. W. B. Davis, of Cincinnati, in his paper first related the case of a person who was refused a policy by a life insurance company because of the presence of albumin in the urine, yet a thorough study of the case convinced him that the individual was free from any form of disease.

A review of the literature showed that such cases were not uncommon, and the form of albuminuria had been spoken of, according to the case, as dietetic, non-organic, intermittent, remittent, recurrent, paroxysmal—from muscular exertion—latent, simple, transient, postural, physiological, psychical, adolescent, mechanical, etc. These terms pointed to some of the demonstrated or supposed causes. The profession had made really but little progress in the study of albumin in the urine since the time of Bright, and had made the mistake of looking upon all cases of albuminuria as of grave significance.

Dr. Vaughn had examined the urine for albumin in numerous cases, and could say that where it was constantly present there was some form of Bright's disease, which would eventually kill the patient. In almost any individual, however, albumin might appear temporarily in the urine at some period of the day, and in such case it was due to some derangement of digestion or of the liver. This form he spoke of as periodic albuminuria.

Hydrophobia.—Dr. Harold N. Moyer, of Chicago, read a paper on the "Clinical Study of Hydrophobia, with Statistics and Report of Cases." There were those who took the view that hydrophobia was only a modified psychosis. This view was combated in the paper, which reviewed the twenty-five cases of deaths from the disease reported to the health authorities in Chicago from 1881–88. The youngest patient was two and one-half years of age, the eldest sixty. The longest duration of the disease after the period of incubation was five days; the shortest, one day; the average in nineteen cases was three days. The average period of incubation was about forty-one days; the shortest was seventeen days.

There might be nervous symptoms resembling hydrophobia in milder degree, but it appeared unreasonable that in all the reported cases, ending so often in death, most terrible symptoms could depend only upon the imagination of the patient. The type of the disease as it had been described in this country corresponded with that in Europe.

The author held that hydrophobia was a distinct infec-

tious disease; that it was not a psychosis, and bore little or no relation to diseases of the mind.

Pasteur's Preventive Inoculation of Rabies.—Dr. A. Lagoris, of Chicago, in his paper, reviewed in a clear and terse manner the work of Pasteur, and the results of his method of inoculation as it appeared in the statistics. He was a strong believer in the infectious nature of hydrophobia, and in the success of Pasteur's method of inoculation.

OBSTETRIC SECTION.

First Day, Tuesday, May 20th.

The Section was called to order by the President, Dr W. W. Potter, of Buffalo, who immediately proceeded to give his address.

The President's Address.—He digressed somewhat from the usual order of things, and gave some new ideas as to how the Section should be conducted. He advised that the secretary be elected for a longer time than one year, as in that time he only learned how to be of service and became acquainted with the members. He would have an assistant secretary elected each year, probably from the place of meeting. He dwelt at length on the importance of a prompt and full report of the proceedings of the Section in pamphlet form. He advised the securing of a stenographer, as it was almost impossible to get the doctors to write out their discussions, or abstracts of their papers, even for that most amiable personage the medical journal editor. He also thought there should be a vice-chairman elected to fill the place of the chairman in case of unavoidable absence.

Progress in Obstetrics.—The doctor then proceeded to refer to a few points in progress in obstetrics and gynecology during the past year. The practice of surgery had not been more revolutionized by Lister than that of obstetrics. The first lesson is that the parturient woman must be clean. Then followed a discussion on antiseptics. Traction forceps came in for a share of attention. He thought them serviceable in some cases and not to be so sweepingly condemned as on their first appearance. Their assistance often enabled us to save both mother and child, one of these instances being where impaction of the head is accompanied by uterine inertia. In discussing the advances in gynecology considerable time was devoted to the amputation of the cancerous uterus. He thought the present operation for either cancer of the body or neck, or epithelioma of the cervix, was total vaginal extirpation of the uterus.

Electricity in Gynecology came in for a share of consideration. Electricity, he said, was in the air. He discussed the treatment by electricity of uterine myoma, and also that of ectopic pregnancy by the same means. In the latter he favored abdominal section. Electricity will be adjudged a place in gynecology, but this place is not yet fixed.

On motion, that part of the President's address relating to the workings of the Section was referred to a committee of three.

Dr. Alexander Dunlap, of Springfield, O., the veteran laparotomist, was present and invited to a seat on the platform.

Early Operation for Cancer of the Uterus.—Dr. Franklin H. Martin, of Chicago, read a paper on the subject, "A Plea for Early Vaginal Hysterectomy for Cancer of the Uterus." Dr. Martin had collected one hundred and thirty-four cases which had been performed since January 1, 1885, with the idea of getting at the future immediate mortality of this operation. The mortality was less than fifteen per cent. Of 25 operations, 4 had been operated on but once; 3, twice; 2, three times; 3, four times; 5, five times; 1, eight times; 1, twelve times; 1, thirteen times, and 1, twenty times. The average mortality of operators having the largest number of cases was but ten per cent. A summary of Dr. Martin's paper is as follows: 1. Vaginal hysterectomy is the most justifiable surgical procedure we know as yet for cancer of the uterus. 2. Vaginal hysterectomy should be attempted for cure of cancer of the uterus at the earliest possible moment after the disease is diagnosed. In support of the foregoing propositions these facts were given: *a.* Vaginal hysterectomy will remove the entire disease in cancer of any portion of the uterus in a greater proportion of cases than any other surgical procedure now recommended. *b.* Vaginal hysterectomy will enable the operator to go farther beyond the diseased tissue into healthy tissue than any other surgical procedure. *c.* Vaginal hysterectomy is a more ideal surgical operation and leaves the remaining tissues in a less favorable condition for return of the disease than will any other operation. *d.* Vaginal hysterectomy for cancer of the uterus will in the future give an immediate mortality among general operators of not more than ten per cent. In the hands of experts it will not exceed five per cent.

Dr. L. H. Dunning, of Indianapolis, could not agree with the essayist in the sweeping assertion that total extirpation of the uterus was the operation *par excellence*. Any operation must fail unless all diseased tissues are removed. If the cervix is primarily affected, and only a part of it, removal of the cervix is all that is necessary. Hoffmeier's statistics show us that the amputation of the cervix is of less danger primarily, and the longevity of the patient is greater. The speaker had done twenty-five high amputations of the cervix without a death. We should not remove the whole uterus in every case of epithelium or affection of the cervix.

Dr. H. Graff, of Eau Claire, Wis., had a case so much in point that he thought it worth reporting. It had been stated by the previous speaker that cancer was a local disease, but he queried the truth of this fact.

Dr. T. A. Reamy, of Cincinnati, read the statistics of Dr. A. Martin, of Berlin, which he presented to the International Medical Congress at Washington. The speaker believed that skill will bring the operation to such perfection that it will not be a primarily dangerous one. As the Fallopian tubes are a part of the uterus, why would you remove the uterus and leave a part of it behind? Will anyone deny the anatomical and physiological proposition? He reported a case where he removed a cancerous cervix seven years ago. The specimen was submitted to Dr. Kebler, of Cincinnati, one of the best pathologists in that city, and under the microscope it proved to be cancer. This patient is still living and has two healthy, happy children. He had two other cases where he had done the same operation and the patients also bore children. Had I removed this uterus the result could not have been better; the dangers would have been greater and she would not have had these children. If cancer commences in the body of the uterus any man who would recommend any other operation than total extirpation would be foolish and dangerous. Why do so many cases of high amputation get well? Why have advertising quacks been able to remove mammary glands with arsenic paste, and the disease did not return, when in similar cases in which we have operated it does return? The less traumatic surface you can have, if you remove the whole disease, the better The less surface you have, and open vessels for absorption, the less danger you have for recurrence.

Dr. Wm. H. Wathen, of Louisville, was of the opinion that in a great many cases where amputation of the cervix had been made for cancer and the patient recovered, the diagnosis, be it either clinical or microscopical, was incorrect.

Dr. J. L. McIntyre, of St. Louis, wished to enter his earnest protest against the assertion that total extirpation of the uterus is an ideal operation.

Dr. Martin closed the discussion and cited a case on which he was operating before the class at Chicago, and Professor Byford came along and told him to amputate the cervix and let the rest alone. He removed the entire

uterus and presented the specimen at the Chicago Gynecological Society, where it was cut open and the disease found to extend in a narrow line clear up to the fundus. This was examined by the pathologists of the society and found to be carcinoma.

SECOND DAY, WEDNESDAY, MAY 21ST.

Election of Officers for the Section resulted as follows: *President*—Dr. C. A. L. Reed, Cincinnati; *Secretary*—Dr. H. A. Kelley, Baltimore.

Stricture of the Urethra in Women.—DR. ELY VAN DER WARKER, of Syracuse, N. Y., read a paper on this subject, in which he thought the frequency and seriousness of this condition of the female was not sufficiently appreciated. The most of the strictures he thought to be of the annular variety and situated near the meatus. He had had no experience with electrolysis, but was of the opinion that it would only prove irritating to a sensitive urethra. The sound he considered utterly misleading and could not give an exploration of the parts. We should use instruments which might be called those of precision, viz., the exploring bulbs.

DR. ANDREW F. CURRIER, of New York, spoke of the toxic form and described a case occurring in his practice due to cantharides. Stricture in the male has been overestimated. Many cases are treated where treatment is unnecessary.

DR. GEORGE J. ENGLEMAN, of St. Louis, said that this frequency of stricture in woman was something new to him. He would ask the essayist was it not an inflammatory condition rather than a narrowing. He has not used electrolysis, but a mild sedative current, the positive pole of the galvanic battery, will act as a sedative to the irritated nerve and will often accomplish what Dr. Van der Warker seeks by dilatation.

A Self-retaining Catheter.—DR. C. B. REED, of Middleport, O., had found a self-retaining catheter worn a part of the time to be very valuable. He once had a violent case of peritonitis follow the dilatation of the urethra.

DR. A. F. CURRIER, of New York, read from the title, "A New Operation for the Relief of Prolapsus of the Anterior Vaginal Wall." The doctor thought that lesions of the anterior vaginal wall had not been given the importance they deserved. And this importance is an argument in favor of its treatment. Prolapse may occur outside of parturition. The operation described was an oval cross-shaped denudation, the edges of which being approximated dispelled the prolapse. He had made the operation three times, but the time elapsing—five months—was hardly sufficient to decide as to the permanency of the relief, but everything pointed that way. As for cicatrix, no one would know that an operation had been performed.

DR. ELY VAN DER WARKER, of Syracuse, N. Y., thought the operation well devised to cure the trouble, but if he should offer any criticism it would be that more denudation should be made in the lower part of the vagina. He had made a number of successful operations after Dr. Reamy's method, which has for its essential feature the going deep into the connective tissue and giving a strong support to the sutures.

DR. T. A. REAMY, of Cincinnati, remarked that it was very important to go deep. He uses silk sutures. Suppuration does not occur after using catgut. He uses this suture also, but it may give out too soon. He leaves his sutures in two and even three weeks.

DR. A. W. JOHNSTON, of Danville, Ky., thought ectropion of the bladder much like ectropion of the eyelids. Ophthalmologists used to cut away the redundant mucous membrane till they found the ectropion was due to the shape of the eyelids. In ectropion of the bladder we should repair the perineum. If the posterior part of the vagina is attended to the anterior wall will have its support and will not prolapse.

DR. GEORGE J. ENGLEMAN, of St. Louis, said that his own experience with this operation had been unsatisfactory. He thinks it only profitable as an adjunct to the operation on the posterior wall.

DR. ALEXANDER DUNLAP, of Springfield, O., was not in favor of leaving sutures in two and three weeks, but removed them on the third day.

A telegram was read announcing the sudden death of Dr. W. H. Byford, of Chicago.

The Surgical Treatment of Non-Pedunculated Abdominal Tumors, was the subject of a paper by DR. HENRY O. MARCY, of Boston. After reviewing in brief what is known of the origin and development of the cystic growths of the pelvis, the writer stated that, developing beneath the deeper structures, they necessarily are inclosed by the peritoneum as an investing membrane; and that the demonstration made years since by the late Dr. Miner, of Buffalo, N. Y., has special value in this class of cases—the enucleation of the cyst by what he called the process of stripping the peritoneum from it. This Dr. Miner recommended in all the ovarian cystoma without regard to the formation of a pedicle. For obvious reasons this method thus generally applied fell into disuse, and has been largely forgotten. In that class of cases, however, where the development has left so broad an attachment that there is wanting a pedicle Dr. Marcy advocates a modification of the method as presenting many advantages. This he practises as follows: After a partial emptying of the cyst contents, the peritoneum is divided at a considerable distance from the base of the tumor and the cyst is enucleated. The bleeding vessels are temporarily secured and the peritoneal pocket thus formed is seized with large compression forceps and held by an assistant. The base, and if possible, which is surely not difficult, quite beneath the attachment of the cyst, is sewed evenly through with an even continuous tendon suture, in double stitch, effected by means of a long covered needle, set in handles, with eye near the point, and generally known to the profession after the name of the author. This suture encloses all the tissues and, when properly placed, not only controls hemorrhage but constricts without necrosing the tissues. The superfluous structures are cut away to within an inch of the sewing and the edges are intra-folded by a continuous tendon suture, the line of the stitches being taken parallel to the cut edges. This method of adjustment allowed of the replacement of the parts without strain or tension and closure of the abdominal wound without drainage. Dr. Marcy also advocates and practises the basic uterine tissues after the removal of the fibroid tumors in a similar manner, his first observation and studies on the subject having been published about ten years ago. They are all founded upon the use of the buried animal suture (tendon for many reasons much prefered), itself aseptic, as aseptically applied in an aseptic wound. Dr. Marcy then showed his tendon sutures, which are taken from the kangaroo's tail, which he has prepared and sent him from Australia.

DR. T. A. REAMY, of Cincinnati, in discussing the paper said he was not so dumfounded by these cases as formerly, but had lost one case operated on before the class during the past winter. It was because the adhesions were so great. He should have abandoned the operation, introduced drainage, and left the cyst in situ.

DR. MARCY, in reply to a question, said that he would not under any circumstances use a drainage-tube unless there was a septic condition present.

SECTION ON DISEASES OF CHILDREN.

FIRST DAY, TUESDAY, MAY 20TH.

DR. I. N. LOVE, OF ST. LOUIS, CHAIRMAN.

IT was voted that the section of dietetics be invited to meet during this session with that of pædiatrics.

The Annual Address of the Chairman was deferred until the second day.

Operative Treatment of Acute Peritonitis in Children.—Dr. G. Frank Lydston, of Chicago, Ill., read a paper entitled, "A Plea for Early Operative Treatment in Acute Peritonitis, with Special Reference to the So-called Idiopathic Peritonitis of Children." Before the introduction of the opium treatment by Clark in 1850, nearly all of these cases resulted fatally. The ideas of Clark held sway for forty years. A reaction against this view was now strongly setting in. Septic cases had in time past been treated in precisely the same manner as non-septic cases. This was manifestly an error. The modern view regarding the nature of peritonitis is that it is essentially a surgical, rather than a medical affection, and the writer made a strong plea for early operative interference. He did not believe there was any such thing as "idiopathic" peritonitis. To attribute it to cold, dietetic errors, and such like causes was simply to express our ignorance. It was undoubtedly a sequel to certain constitutional conditions; gout, tuberculosis, for instance, of renal, and puerperal affections, but he was inclined to regard traumatism as by far the most common cause in the so-called idiopathic cases. To trace out this traumatism was not always easy. It might be nothing more than a rough manipulation of the abdomen or ovarian compression as practised in cases of hysteria. Both of these procedures have caused the disease. Children more frequently than do adults suffer from the idiopathic variety. In them, the weight of the abdominal viscera is considerable, more so proportionately than in grown persons, while nature's protection, viz., the peritoneum and abdominal wall are structures of correspondingly less resisting power. A child cannot always tell what slight traumatism it may have sustained. Straining at stool, and blows upon the abdomen, especially when the stomach is full, are fertile causes. In the latter there is no external bruise. The bladder may be bruised by external violence when it is full, and even when empty a similar force may wrench its peritoneal attachments, and so light up internal trouble. In many cases the concussion produced by trifling jars and shocks is far-reaching in its consequences. There is a strain or rupture of the retentive peritoneal bands which hold the different viscera in place. From all these apparently insignificant causes local or general peritonitis may be set up. Many cases arise from previous cæcal and peri-cæcal trouble. Peritonitis following catarrhal inflammation in this region is far more common in children than in adults.

Now why is the diagnosis not made earlier in children? The reason is, the rapid extension of the inflammatory process before localization can be definitely made out. The early abdominal swelling precludes a satisfactory examination, and the lymph exudation does not have time to form before a general involvement occurs.

In regard to treatment, we have swung from opium to free saline purging. This latter the writer regarded as an objectionable extreme. The ancients opened the abdominal cavity in peritonitis, and we were returning to the same plan. The operation was a recognized one. Like all operations it had its limitations. In many cases a simple exploratory incision was all that was necessary. Opium and warm fomentations could be tried at the start, but if the case did not respond to such treatment, incision should be no longer delayed. The arguments were: 1. The analogy of the peritoneal process to that of other serous membrane inflammations. The relief of tension always assisted nature by the withdrawal of injurious influences or the sympathetic ganglia. 2. The removal of abdominal fluid lessened pressure on the heart. So also did the puncture of the gut with a fine needle, which allowed the escape of air and gas. It was his practice to also flush out the abdomen with hot water, either plain or weakly saline. A weak solution of boracic acid was also of service. Moderate dosage of salines could then be used. Operation did not jeopardize recovery. No case should be allowed to die without it.

Dr Hobart A. Hare, of Philadelphia, believed that we could cure many cases with opium and calomel. Hutchinson had suggested belladonna. Fitz, of Boston, had collected a large number of statistics on the subject. Medical treatment gave seventy-two per cent. of recoveries, while surgical treatment gave only eleven per cent. If the disease was due to perforation of the gut, salines would only increase the damage. He believed cold to be a very frequent etiological factor. In a sthenic case, the effused fibrine would organize; in an asthenic case the effused serum would be absorbed. Hence there was here no indication for operation.

Dr. John A. Larabee, of Louisville, also believed that opium would cure many of the cases caused by cold. He regarded constipation as a common factor. He frequently met with it in school children, where the cæcum sagged constantly on the iliac muscle while they were sitting so much, and allowed fæcal matter to lodge there. Intussusception might simulate peritonitis. Here early operation was advisable. But he had strong faith in opium as an allayer of inflammation as well as of pain. We should early discriminate between septic and non-septic cases.

Dr. I. N. Love, of St. Louis, pleaded for early and complete interrogation of the parents as well as the child regarding an overlooked injury. We should take time to this. We might be greatly helped, by so doing, in making an early diagnosis.

Dr. E. A. Wood, of Pittsburg, said we should not wait after our medical measures seemed to have reached their full effect. As soon as pus was in the abdomen, drugs could no longer help us. He regarded abortion as the most frequent cause of peritonitis in women.

Dr. O'Brien, of Pittsburg, called attention to the marvellous tolerance which some children exhibit toward opium in these cases. To a child in its seventh year suffering with peritonitis he had given fifty-five grains of morphine in forty-eight hours, the patient recovering.

Antipyrine in Children.—Dr. S. Henry Dessau, of New York, sent a paper which was read by Dr. William Perry Watson, of Jersey City. Title—"Therapeutic Value of Antipyrine in Diseases of Children."

He had used the remedy in pneumonia, chorea, pertussis, and urticaria. In pneumonia it not only relieved the temperature but lessened the nervous irritability. Dosage was two and a half grains in water every hour for four doses. Less might prove efficacious. In chorea he had had excellent results in seven cases; dosage here seven and a half grains four times daily. How it acted in chorea he did not know. It might relieve the rheumatic factor at the bottom of so many of these cases. Forty-five cases of pertussis had presented a shorter duration than with his previous methods of treatment. It was the chronic recurring form of urticaria rather than the acute that responded to the treatment.

Dr. Larabee thought that antipyrine caused a dangerous anæmia in many cases. It inhibited the oxygenation of the blood. In both pneumonia and chorea it was safe within limits by dilating peripheral vessels and so lessening the stasis in the lungs in the one case, and the brain in the other. Digitalis often failed us in pneumonia. Dr. Dessau's dosage might cause blueness.

Dr. McNeill, of Pittsburg, had noticed the latter symptoms, but had found that digitalis relieved them.

Second Day, Wednesday, May 21st.

The following papers were read by title "Intestinal Diseases of Children," by Dr. J. B. Pritchard, of St. Louis, Mo.; "Chloral Hydrate in the Treatment of Scarlatina," by Dr. J. C. Wilson, of Philadelphia, Pa.; "The Significance of High Temperature in Children," by Dr. W. L. Stowell, of New York City; "Phenacetin in Whooping Cough," by Dr. J. T. Winter, of Washington, D. C.; "Further Observations upon Tooth and Mouth Disease in Relation to Human Scarlatina as a Prophylac-

tic," by J. W. Stickler, of Orange, N. J.; "Tinea Capitis," by Dr. H. T. Dixon, of Evansville, Ind.; "Over-Medication during Childhood," by Dr. B. F. Hart, of Sweet Springs, Mo.; "Does Alcohol Conserve Tissue?" by Dr. E. Chenery, of Boston, Mass.; "Feeding in Wasting Diseases," by Dr. Ephraim Cutter, of New York City.

The Value of Sulphonal in Children's Diseases.—Dr. William C. Wile, of Connecticut, sent a paper with this title, which was read by the Chairman, Dr. Love, of St. Louis. Sulphonal was the ideal hypnotic. It was without the bad effects of opium and the uncertainty of the bromides. It could be given in ten-grain doses. It quieted reflex irritability. It did not constipate nor disturb the stomach. In one case in which a drachm was taken accidentally in ten-grain doses, there was a deep slumber lasting twenty-four hours, slight fever, but a normal pulse and respiration.

Atropine in Enuresis.—A paper, by Dr. R. B. James, of New York City, on "The Value of Atropia in Enuresis," was read by Wilson Cummings, of Bridgeport, Conn. He had used the remedy in doses of one one-hundredth of a grain, at six and at nine o'clock every evening. It acted well in nearly every case at the start. After the enuresis was once checked, it could be controlled by a smaller dose, but if the drug was discontinued a relapse would nearly always follow. In some of the favorable cases without relapse the writer had thought that the children outgrew the condition. Atropine could not be regarded, in his judgment, as a specific.

Dr. W. P. Watson, of Jersey City, had had to modify the very optimistic view expressed by himself at the meeting last year. His later experience had coincided with that of Dr. James. The passage of a sound might cooperate in the treatment and render less atropine sufficiently powerful.

Dr. Hare, of Philadelphia, preceded the use of atropine by that of an alkaline diuretic and diluent. The general experience of those present coincided with that of Dr. James.

Acute Rheumatism in Children.—Dr. F. S. Carson, of Boston, Mass., read a paper with the above title, which was a general *résumé* of the subject. He had found the combination of sodium bicarbonate with the salicylate to be of service.

Dr. Lewis, of Pittsburg, believed that in the early stages of the disease aconite could be advantageously used with the salicylates.

Several present had observed albuminuria as a result of salicylic medication.

Milk Sugar in Infant Feeding, was the title of a paper by Dr. E. F. Brush, of Mount Vernon, N. Y. The literature concerning this remedy was meagre. The commercial product, as used in "Meiggs's Mixture" for infants, had spoiled the milk in one case under his observation. Why, he did not know. Milk sugar in commerce came crystallized on a cob, and also as a coarse powder like barley-sugar. This article was not identical with the lactose as it occurred in the milk. The latter was all absorbed in the infant system, while the former was eliminated by both the urine and fæces. He had proved this latter point with Fehling's test. Milk sugar fermented with great difficulty. The commercial article contained about ninety-five per cent. of the true chemical compound, but it also contained many other crystallizable bodies as well as alkaloids of ptomaines. He believed that cane sugar was preferable to milk sugar as an addition to baby foods, but also that the effect of the sugar was over-estimated in any case.

Feeding in Wasting Diseases.—Dr. Ephraim Cutter, of New York City, read a paper with the above title, prepared by Dr. O. S. Phelps, of California, of which the points were as follows: 1. Don't blindly keep a child on the mother's milk if the latter is poor. 2. Don't add sugar to milk in any event. 3. The milk should be sterilized. 4. If milk cannot be borne at all, use beef essence and pepsin. 5. The so-called infants' foods are practically useless. 6. Even if a child could digest them, it would probably do just as well on milk thickened with the powder of twice-baked bread. 7. Many of the popular processes for removing the casein from milk are useless. 8. Solid general food should not be given till five years have been passed. 9. The bread made from entire wheat flour was preferable to that from the fine flour, as the latter was deficient in tissue-building materials.

Dr. E. F. Brush believed that the sterilizing processes "devitalized" the milk. What the "vital influence" was, we could not say, but there was some such thing. If we could be sure of getting pure uncontaminated milk, it was better not to sterilize it. He believed that our city milk supply would be benefited if consumers were willing to pay a higher price to some reliable man who would conduct his dairy business in accordance with our modern sanitary ideas.

Dr. E. O. Wood, of Pittsburg, Pa., believed that milk should be directly strained into a jar at the dairy, and then hermetically sealed. In that way it could be placed in the hands of the consumer in a pure state. He disapproved of using scale pepsin, preferring the glycerole of pepsin or some other fluid preparation. He used cane sugar rather than milk sugar.

Dr. Frank Woodbury, of Philadelphia, described a cheap sterilizing apparatus he had devised. He made the point that calf pepsin was far superior to hog pepsin in the predigestion of milk.

Dr. I. N. Love believed in a public regulation of the milk supply of large cities, as is now done with water. Certainly the former was practically as important as the latter.

Dr. Brush had found that milk could be better kept in dark-colored bottles than in those of plain transparent glass.

(To be continued.)

ASSOCIATION ITEMS.

The Committee on Dietetics.—In the general session on Thursday, the chairman of this committee, Dr. E. O. Wood, of Pittsburg, delivered his address, taking for his subject "Mastication as a Factor in the Development of the White Race in America." He took the view that the nation was slowly being destroyed by means of too well prepared food, whereby the necessity for mastication was in great measure removed. If children were given food which must be well chewed, and were compelled to moisten the bolus with their own saliva rather than allowed to wash it down with large draughts of tea, coffee, or other fluid, then their jaws would be well developed. There would be plenty of room for the teeth, and the jaws would be large enough to permit of a normal blood supply to them. Thus dental caries would be prevented, the beauty of the coming race would be preserved, and we would become a race greater in body and mind than the ancient Greeks. He begged his hearers to warn their patients against the evil consequences of neglecting to impress upon their children the obligation of mastication, and hoped that the rising generation would not be allowed to barter away its birthright for a mess of pottage or any other soft food. The speaker apparently forgot to note nature's instinct of self-preservation in substituting the chewing of gum for that of fried steak and other to-be-masticated food.

The Exhibits.—A fine display of drugs, surgical appliances, etc., was held in the Amusement Hall on Broad Street. Almost every one of the large manufacturing firms in the country was represented, and delegates and townspeople came from the building loaded down with invalid-foods and medicines enough to supply the ordinary needs of a suffering mortal for the next twelvemonth.

The Social Features.—On Tuesday evening a public reception was held in the Hall of Representatives at the Capi-

tol. On Wednesday afternoon there was a reception given by the ladies of Nashville to the wives and daughters of the delegates, in the Maxwell House. In the evening of the same day there was a concert in honor of the Association at the Vendome Theatre, and there were also three receptions given by citizens of Nashville in their own homes. On Thursday there was an excursion to the Hermitage, the home of Jackson, and in the evening a number of private citizens threw open their houses for the entertainment of the visitors. Finally, on Friday there was an excursion to the celebrated Belle Meade stock farm, situated about ten miles from the city. Many of the members of the Association availed themselves, upon their homeward journey, of the privilege accorded them to stop over a few hours to visit Mammoth Cave.

Hotel Accommodations.—We were taken to task a year ago for offering an objection to holding the meeting in Nashville on the ground that the hotels would be insufficient to accommodate all who might attend. But the event has justified our fears, for many delegates were unable to find accommodation at the hotels, and many more who found a place to sleep were not comfortable, and could not be made so by reason of the crowd. The attendance at the meeting was fortunately below the average, otherwise the sum of discomfort would have been extreme. The membership in the Association has grown to such proportions that none but the largest cities in the country can afford accommodations for those attending the meetings.

The Tennessee Pharmaceutical Association.—The third annual meeting of this society was held in Nashville during the meeting of the American Medical Association. Mr. W. L. Dowdy, of Memphis, was the president.

He Wanted to Attend Both.—After the Committee on Nominations had made its report, fixing upon the first Tuesday in May as the date for the next meeting, a member rose and said, somewhat excitedly, that that time would never do—it must be changed—for the East Tennessee Medical Association met at the same time, and if the date were not changed no member of the latter Society would attend the American Medical Association meeting. The other delegates thought, however, that it would be more simple if the East Tennessee Medical Association made the change in the date of its own meeting, and the member sat down again.

The Change in the Place of Meeting.—When the Committee on Nominations reported that San Francisco had been selected as the place for the next meeting there was but faint applause. Then a Philadelphia delegate recalled the fact that it had been determined to meet in Washington every second year. This seemed to meet with instant approval, which was not to be moved by the eloquent words of a member of the Omaha Medical Society, setting forth the beauties and the grandeur of that city, which (had not the lithographer disappointed him) he would have shown by a map to be the exact centre of the United States, if not of the universe. To Washington the Association was bound to go, and so it voted, almost unanimously. This necessitated a change in the Committee of Arrangements, and Dr. D. C. Patterson, of Washington, was nominated to fill that position.

The Many Bronzed Faces, surmounted by broad-brimmed felt hats, among the delegates, bore evidence to the fact that the place of meeting was in the South. The pale faces from the North looked a shade lighter when contrasted with the sunburnt features of their Southern brethren.

The Presidential Nominations.—For some years past the younger members of the Association have felt that they were not properly represented in the governing body, and this year they made a determined effort to capture the presidential chair. Two candidates were presented to the consideration of the Committee on Nominations, namely, Dr. Briggs, of Nashville, and Dr. J. W. Matthews, of Louisville. The latter was the young men's candidate but his friends soon saw that they could not gain their point, and Dr. Briggs was nominated on the first ballot by a substantial majority. The nomination was then made unanimous.

The Meeting a Third of a Century Ago.—This is the second meeting of the Association in Nashville, the first having been in 1857. At that time a grand ball was given in the Capitol in honor of the attending delegates. Of six members of the invitation committee four survive, and were present at this meeting. These are Drs. J. H. Callender, W. L. Nicol, T. L. Maddin, and C. L. Lewis.

To Enforce the Leprosy Laws.—In the Section on State Medicine, Dr. Lee, of Philadelphia, introduced a resolution recommending the American Medical Association to urge a stringent enforcement of the leprosy laws. He said that he had been informed by a physician of New Orleans that there were forty-two cases of leprosy in that city. This resolution was strongly opposed by Dr. Baker, of Michigan, who thought the time of the Association should not be taken up with leprosy when there were so many vastly more important measures demanding consideration. For his part, he would as willingly vote for a resolution calling for the national control of chicken-pox as for that of leprosy. Dr. Reeve, of Wisconsin, denied that leprosy was on the increase. Surgeon-General Hamilton, of the Marine Hospital Service, said that a very strict outlook for leprosy was being kept at all the sea-ports, and two lepers had already been sent away since the law went into effect. There were, however, a number of lepers at large in Key West. After some further discussion Dr. Lee's resolution was tabled.

The Medico-Legal Aspects of Laparotomy.—At a meeting of the Section on Neurology and Medical Jurisprudence, on Wednesday afternoon, an animated discussion was held in regard to the medico-legal relations of abdominal section. Papers were read and the discussion was participated in by Drs. Yandell, of Louisville, W. W. Potter, of Buffalo, Moyer and Kernan, of Chicago, McIntyre, of St. Louis, Crawford and Shimwell, of Pennsylvania, Marcy, of Boston, and Manly, of New York. The general opinion arrived at was that, though this operation might save life in certain cases in which death was inevitable without it, it should, nevertheless, be resorted to only when absolutely necessary, and even then not by everybody but only by those to whom a long surgical experience had given a high degree of operative skill.

A New Section.—In the report of the Committee on Dietetics presented at the general session on Thursday, a resolution was offered creating a new section, to be known as the Section on Dietetics and Physiology. This resolution was approved by the Association.

No More Discussions from the Stage.—Most of the subjects introduced during the general sessions are discussed chiefly by the older members of the Association, many of whom occupy seats on the stage, in virtue of the fact that they are usually ex-presidents, and are invited to take this place at the opening session. At the close of Thursday's meeting a delegate offered a resolution that in future meetings of the Association, the business of the general sessions shall be conducted entirely from the floor of the house, and no one occupying a seat on the platform, the secretary alone excepted, shall be recognized by the president. After some discussion the resolution was adopted, with an amendment permitting the president to recognize also the chairman of the committee on arrangements even though he might be on the stage.

The Army Delegates, detailed by the Secretary of War to represent the army medical department, were Dr. J. D. Baxter, chief medical purveyor of the army, and Surgeon A. A. Woodhull.

None but Members to be Admitted.—At the closing session a motion was made that cards be given to the members and delegates after they had registered and paid their dues, and that no one should be admitted to the general sessions during the first two days except upon presentation of this card. The object of the motion, as explained by Dr. Moore, was to keep out loungers, loafers, and dead beats generally. After some discussion, and several attempts to improve upon the suggestion by way of amendments, it was carried.

The Medical College Convention.—A meeting of the National College Association was held on Wednesday afternoon. The following officers were elected: *President*, N. S. Davis, Chicago; *First Vice-President*, Aaron Friedenwald, California; *Second Vice-President*, H. N. Didama, Syracuse, N. Y.; *Third Vice-President*, T. Menees, Nashville; *Fourth Vice-President*, Sam Logan, New Orleans; *Fifth Vice-President*, W. H. Pancoast; *Sixth Vice-President*, C. A. Lindsay; *Seventh Vice-President*, W. T. Peck; *Secretary and Treasurer*, Perry H. Millard, of St. Paul, Minn. The business committee recommended that all the colleges of the Association adopt a three years graded course; that the examination be both oral and written; that laboratory instruction in chemistry, pathology, and histology be required; that an admission examination be held, and that the secretary of each college transmit to the secretary of the Association a list of all the matriculants in his institution, together with a copy of the questions asked at the examination for admission. At the general session of the American Medical Association on Thursday, the secretary of the college Association presented a report setting forth in detail the rules adopted by the Association, which report was accepted with expressions of hearty approval by the general body.

The Section on Dermatology had some difficulty in finding a place to assemble, and held no meeting the first day. On Wednesday, however, the section accepted the hospitality of Dr. Morrison, of Nashville, and met in his office, where some interesting papers were read.

The Address on State Medicine.—Dr. A. L. Carroll, of New York, who was to deliver the address on State Medicine, did not respond when his name was called. The explanation was made that he was unable to attend the meeting, and that his address was already printed in the *Journal*, so it was read by title merely.

A Section on Materia Medica and Pharmacy was created. It is, like the Section on Dental and Oral Surgery, to have its own autonomy, and is to have a membership composed of both physicians and pharmacists.

Dr. J. M. Toner resigned his position as trustee of the *Journal*, and the vacancy so created was filled by the election of Dr. Moore.

Down on Ready-made Prescriptions.—During the last session a resolution was presented from the Tennessee Pharmaceutical Association, in session at the same time in Nashville, calling upon the American Medical Association to discountenance the use of the numerous proprietary compounds so persistently urged upon the attention of the profession. The resolutions were accompanied by an appendix setting forth the reasons for their adoption, mentioning in particular several much-advertised articles which were said not to correspond in their composition to the published formulæ. The communication was accepted and ordered to be printed in the *Journal*.

A Vote of Thanks was tendered the Secretary, Dr. Atkinson, who had so faithfully and efficiently served the Association for a quarter of a century.

The Vaccination Centennial.—It was resolved that the President of the Association appoint a committee to make arrangements for the celebration, in 1896, of the centennial of the discovery of vaccination by Jenner.

The Association of Medical Editors held its annual meeting on Monday evening in the lecture-room of the Vanderbilt Law School. The meeting was called to order by Dr. C. S. Briggs, and the address of welcome was delivered by Dr. J. Berrien Lindsley. Dr. I. N. Love then delivered the presidential address. He said that the complaint had often been made that there were too many medical journals, but he did not think so. As long as good work was done by any journal it had a right to exist. The law of the survival of the fittest would obtain here as well as elsewhere. Dr. F. L. Sims, of Memphis, read a paper on "The Needs of Medical Journalism," in which he urged especially that the prominent evils of the secular press be avoided at the same time that its enterprise be emulated. Dr. T. D. Crothers, of Hartford, presented a communication on "The Progress of Medical Literature," in which he took a very hopeful view of the future of medical journalism. Dr. Culbertson, of Cincinnati, thought that a medical editor should devote his whole time and energy to the care of his journal, making of journalism a real specialty. The following questions were proposed for consideration at the next meeting of the Association:

1. What has been the real effect of the rapid increase of free hospitals and dispensaries in all the larger cities, ostensibly for the care and treatment of the sick poor, during the last twenty-five or thirty years; first, upon the poor, and, second, upon the people as a whole?
2. What has been the effect upon the real interest of the medical profession?
3. What are the duties of those controlling the medical press relating to the foregoing questions?

The election of officers resulted in the choice of the following: *President*, Dr. F. L. Sims, Memphis; *Vice-President*, Dr. Frank Woodbury, Philadelphia; *Secretary and Treasurer*, Dr. J. C. Culberson.

The Association then adjourned to meet at dinner in the Baxter Court Café.

A Study of Endocarditis.—Twelve cases of endocarditis in man were examined by Dr. Wyssokowitsch. In the cases of acute and chronic endocarditis no micro-organisms were found; in the ulcerative cases, staphylococcus pyogenes aureus was found and cultivated. Malignant endocarditis, similar to that seen in man, was induced in rabbits by injuring the valves by means of a sound introduced into the left side of the heart through the right carotid, and then injecting the streptococcus pyogenes into the veins of the ear. The lesions were necrotic rather than inflammatory; and the same applied to the various emboli in the organs. The vascular lesions due to the micro-organisms occurred where the probe had rubbed the mitral valve, aorta, and carotid, as well as on the torn aortic valves. If the injection was made without passing a probe, or more than two days after its passage, no endocarditis ensued. When staphylococcus was used instead, the lesions were more decidedly suppurative, and the infarcts were suppurative rather than anæmic necroses. When the probe was introduced, but no injections made, there was no reaction at all. The micrococcus tetragenes, the bacillus pneumoniæ, and the septic coccus of Nicolaier produce similar results. It is noteworthy that the merest graze of the probe was sufficient to determine a malignant endocarditis if the animal were infected with micro-organisms within two days, but not afterward.—*The London Medical Recorder.*

Early Maternity.—It is reported in *The Lancet* that a girl, aged thirteen years and eight months, recently gave birth to a boy in the Vienna Foundling Hospital. The boy does not weigh quite three pounds, and is not likely to live.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, held in the Army Medical Museum, Washington, D. C., May 13, 14, and 15, 1890.

SECOND DAY, WEDNESDAY, MAY 14TH—MORNING SESSION.

(Continued from page 605.)

The Radical Cure of Hernia.—This was the subject of a paper by DR. W. T. BULL, of New York. The present paper was based upon the operations for the radical cure of hernia done by the author in the last seven years. The most essential feature of all the operations was the ligature of the sac at the highest possible point. The cases were divided into four series. In the first series, containing 40 cases, the sac was isolated and ligated with catgut. The portion below the ligature was dissected out when small. When large, or when it contained the testicle, it was drained. The wound was sutured and a drain left in the inguinal canal four days.

In the second series, containing 39 cases, the sac was treated as above and catgut sutures were applied to the pillars of the external canal and to the divided aponeuroses.

The third series, embracing 39 cases, was treated by ligature of the sac as before. The anterior wall of the canal was only divided when it was impossible to reach the neck of the sac in any other way. And the canal was sutured with two layers of sutures.

The fourth series embraces 16 operations on children between the ages of four and fourteen years of age. All these operations have been performed in the last six months and the method adopted has varied with the circumstances of the case.

Of the total number, 134 cases, the hernia was reducible in 77, irreducible in 42, and strangulated in 15. All the cases in series four were reducible. In the first series 14 patients were over fifty years of age. In the second series only 5 were over fifty years. This difference was due to my growing conviction that it was undesirable to perform the radical operation after this age except in cases of strangulation. The indication for the operation in children was difficulty in retaining the rupture with a truss, or absence of improvement under this treatment.

There were three deaths in the 134 cases. The first death was in a man of eighty years. The hernia was a large scrotal entero-epiplocele. At the same time the radical operation was performed on a large hydrocele of the opposite side. Death was due to shock and slight hemorrhage into the peritoneal cavity from an atheromatous artery in the omentum being cut through by a ligature. The second death was in a man aged twenty-six with irreducible epiplocele. A large portion of the omentum was ligated, heavy silk being used. Bleeding occurred and it was necessary to reopen the wound and apply a second ligature. Death was due to rapid septic peritonitis. The third death occurred in a case of a large strangulated scrotal hernia of twenty-four hours' duration.

In four cases the intestine was opened in separation of adhesions. These were at once sutured and no bad results followed.

In the first three series primary union has been secured in only about one-half of the cases. In the fourth all of the wounds with the exception of one healed primarily. The exception was in the case of an unruly boy who tore off the bandages.

Observation of these cases has given the following results as regards relapse. In the first series only 22 cases could be traced, with the following results:

Under observation four to five years, 1 case, no relapse.
" " three to four years, 2 cases, 1 relapse.
" " two to three years, no case.
" " one to two years, 9 cases, 1 relapse.
" " less than one year, 7 cases, 6 relapses

Of the second series 20 have been traced.

Under observation three to four years, 1 case, 1 relapse.
" " two to three years, 4 cases, 1 relapse.
" " one to two years, 10 cases, 4 relapses.
" " less than one year, 5 cases, 4 relapses.

Of the third series operated on by ligature of the sac and suture of the canal and ring, 20 cases have been followed. All these operations have been done within one year. There have been 11 relapses. Of the 16 children 5 have presented relapse.

By the first method of operation there has been 63.63 per cent. of relapses in 22 cases. By the second, sixty per cent. of relapses in 20 cases. This seems to prove that there is little to choose between these two methods. Comparing roughly the results by the first two methods with the third by considering the relapses occurring during the first year, we find that in the first series 6, or twenty-two per cent., relapsed in the first year; in the second series, 8, or forty per cent., relapsed in the first year, and in the third series, forty-two per cent. relapsed in the first year.

In regard to the effect of wearing a truss after operation, of the cases that relapsed 6 used the truss, 3 did not. Of the cases that did not relapse, 18 used the truss, 11 did not. I usually direct the patient to wear a light truss to support the weight of the abdominal contents.

I think that the operation is justifiable, for if it does not effect a cure it affords relief for a time, and it is attended with little risk except in the weak and aged. But all methods that have been proposed for the radical cure of hernia will be found unsatisfactory.

Anomalies of Hernia—Lumbar Hernia.—DR. CLAUDIUS H. MASTIN, of Mobile, read a paper on this subject. Since cases of lumbar hernia are of extreme rarity I feel justified in offering the history of a case which came under my observation at birth, and has been kept under notice for the last six years. The child, George H. L ——, was born March 12, 1884. Father and mother are both healthy, strong young people. With the exception of the hernial protrusion the child was healthy and well formed. When the child was two months old my attention was called to "a large wen" on the child's left side. I at once recognized the nature of the protrusion and advised the use of a supporting bandage. This advice was not thoroughly carried out. The case then passed from observation until eighteen months or two years ago. The patient is now a well-grown healthy boy of six years, and although wearing no support, he suffers no inconvenience from the protrusion, which now measures nine and a half inches in its long axis with a transverse diameter of nine inches. To the sense of touch the contents of the hernial sac appear to be the descending colon with a large mass of small intestine. The hernial mass appears to be just beneath the skin and transversalis fascia with no intervening muscular structure. The outer edge of the hernial opening is close against the transverse processes of the lumbar vertebræ. The whole abdominal wall on the left side appears thinned out and weakened. The crest of the ilium supports the lower margin of the protrusion. There is also a direct inguinal hernia on the left side. Two hours after a full meal, the tumor swells up and subsides after kneading.

The small triangular space bounded by the crest of the ilium, the margins of the external oblique and latissimus dorsi muscles, known as the "triangle of Petit," is a comparatively weak spot, where protrusion may take place but strangulation is very improbable. In the 33 cases which I have been able to collate, I find 3 cases only in which anything like true strangulation has taken place. In two an operation was resorted to for its relief. One recovered; the other died. One operation was done in 1738; the other in 1889. In only one case was an autopsy made. This was a case of Dr. Hutchinson's. An interesting feature was the absence of peritoneal sac.

In only one of the 33 cases can the hernia be considered of spontaneous origin. Of the 33 cases 27 were in adults, 6 in children, 3 of which were congenital; 17 were in males and 15 in females; 20 were on the left side, 10 on the right side, 1 on both sides and in 2 the side is not mentioned; 4 followed the track of an abscess. In 11 cases no cause is mentioned, 2 cases resulted from caries and necrosis, 1 was due to old age and prolonged child-bearing, 11 were caused by strains, wounds, or severe injuries. The spontaneous case was in an adult.

It is important that a clear diagnosis be made between lumbar hernia and abscess, tumors of kidney, etc. The knowledge that such a hernia is possible should put the surgeon on the alert.

The treatment consists of little more than protection against injury. In those cases where the opening through which the hernia passes is small and defined and symptoms of obstruction or strangulation become present, it may be proper to resort to a radical operation.

An abstract of the reported cases, 33 in number, with a complete bibliography of the subject, were appended.

Discussion.—Dr. Charles T. Parkes, of Chicago: My experience is based upon less than fifty cases of hernia, in which I aimed at complete removal of the sac, without any attempt at suture of the rings or of the tissues of the canal. I think that a radical cure will be attained as readily when no attempt at suturing the ring and canal is made as when this is done. I think, however, that it is important to remove the omentum in all cases where it is present. I have had the same experience in regard to primary union. In nearly one-half it failed to occur. While the operation is a desirable one, because it gives a certain amount of relief, it does not always effect a radical cure. The removal of the sac is of great importance. In three cases where I was unable to effect complete removal of the sac there was prompt return of the hernia. In two of these cases I subsequently removed the sac, and so far there has been no return. I have had about the same percentage of relapses as Dr. Bull.

Dr. J. R. Weist, of Richmond, Ind.: I have never attempted the radical operation except when operating for the relief of strangulated hernia. I have tried various methods. I think, however, that in every case the hernia has returned after the lapse of one, two, or three years.

The Propriety of the Removal of the Appendix Vermiformis during the Interval of Recurrent Attacks of Appendicitis.—This was the subject of a paper by Dr. Frederic S. Dennis, of New York. The question propounded is a new one, and one which cannot be positively answered at present. The view has been recently advanced that all inflammatory attacks in the right iliac region are dependent upon primary pathological changes in the appendix, and that the subsequent changes are secondary to the appendix disease. This view was not endorsed by the author. He had seen many cases in which the cæcum and pericæcal regions were the parts involved but in which the appendix was normal.

Inflammation in this region may be classed under the heads of typhlitis, perityphlitis, appendicitis, and periappendicitis. These different affections may exist independent of one another.

In determining the proportion of cases in which the appendicitis is recurrent, the statistics of Dr. Fitz were taken, showing that in eighty-nine per cent. the appendicitis is solitary, while in eleven per cent. it is recurrent. In the recurrent cases there are several forms of termination. The attack may terminate in resolution, in the formation of an abscess with the evacuation of pus, and in perforation and general peritonitis. Nearly all authorities agree that the majority of cases terminate in resolution. The whole practical question is with reference to those cases in which general peritonitis, the result of perforation, is likely to arise. If it can be shown that in the extreme emergency of a general peritonitis, laparotomy can save the patient, then the removal of the appendix during the quiescent period is deprived in great measure of the only support that can be claimed for its performance. Perforation does not necessarily preclude the possibility of recovery. Recovery has occurred after perforation, even when laparotomy has not been performed. Cases of this kind were related. It is evident that in the majority of the eleven per cent. recovery takes place. Perforation is the exception, and in some of these exceptional cases of perforation, recovery takes place.

What are the arguments against the removal of the appendix during the quiescent stage in these few cases in which the attacks are recurrent? They are: 1. The danger to life, which is great; 2, the difficulty of a positive diagnosis; 3, the development of ventral hernia; 4, the lack of conclusive evidence that excision of the appendix is attended with permanent relief; and 5, the result of the recurring attacks may afford immunity from danger in the future. Specimens were shown in which the appendix was converted into a fibrous cord, its canal having entirely disappeared.

In some of the cases on which operation has been done, it is impossible to find the appendix, or, when found, it may be adherent to blood-vessels, the ureter, or other important structures.

Taking the clinical and pathological material presented in connection with the fact that operation on the second or third day during an attack of recurring appendicitis is attended with such brilliant results and so light a mortality, is it not wise to decline operating during the quiescent period when the mortality is higher than it is from operation on the second or third day of the attack? From a consideration of the facts, it seems wise to condemn the operation of excision of the appendix during the quiescent period as a routine operation. Some special reasons should exist to justify the operation that are not present in the majority of cases of relapsing appendicitis.

Discussion.—Dr. Joseph Ransohoff, of Cincinnati: I have had no personal experience with operations for appendicitis during the period of quiescence. The majority of these cases of inflammation in the cæcal region have a natural tendency to subside spontaneously. The majority of cases occur in young individuals at a time when the lymph tissues throughout the body are prone to undergo degenerative changes. The entire mucous membrane of the appendix is nothing but a lymph gland spread out. Most cases of appendicitis are of a catarrhal character. In regard to the propriety of withholding operation during the quiescent period, I should agree with the author of the paper.

Dr. John Homans, of Boston: After considering the difficulties and disadvantages of the operation of removal of the appendix during the quiescent period, I should say that if the routine of business or pleasure were seriously interfered with by attacks of appendicitis recurring every three months, and life was filled with apprehension, and if the appendix could be readily reached then its removal might be attempted with propriety.

Dr. J. Ford Thompson, of Washington: Although I have operated many times for acute attacks of inflammation in this region, I have no experience with operations between the attacks. I could only imagine that such operation would be called for in cases which did not completely recover, and in which there was continually discomfort in the region of the cæcum. I have not met with any cases in which the operation seemed called for.

Dr. Wm. T. Bull, of New York: I hold very much the same views as have been expressed by Dr. Dennis. I would take a mild exception to the general condemnation of the operation. I believe that there are cases in which the propriety of this operation is to be considered. If the attacks occur so frequently as to interfere with the ordinary pursuit of business by the adult, or the ordinary amusements of the child, the operation can be considered.

Dr. W. W. Keen, of Philadelphia: My conclusions would be much the same as those of Dr. Bull. In those cases in which many attacks have occurred, the question presents itself strongly to me, would it not have been wise to have operated at an early period and prevented these frequent recurrences which lead to extensive exudation, and increase the difficulty of operation if such should later become necessary. Cases of recurrent appendicitis are dependent not so much upon catarrhal changes as upon ulcerations, concretions, and kinks of the appendix. It is to be distinctly understood that in these cases the operation is simply an exploratory one, and we are to be guided in our subsequent steps by the conditions found.

Meningeal Hemorrhage, Trephining, Ligation of Carotid.—Dr. Joseph Ransohoff, of Cincinnati, read a paper on the above subject. On March 12th, Jos. B——, aged twenty-eight, fell from a ladder a distance of eight feet, receiving a Colles fracture of the left forearm. At no time during the following week did he complain of any symptoms indicative of head injury. The morning of the eighth day he complained of headache and in a short time passed into a condition of unconsciousness. He was seen by the author three hours later breathing stertorously. Temperature normal; respirations, 28; pulse, 40; conjunctival and cutaneous reflexes wanting. Irregular twitching and tossing movements affected the face and extremities of both sides of the body. There was no paralysis. The right pupil was small and sluggish, the left dilated and fixed. The urine had a sp. gr. of 1030 and contained sugar. Examination failed to reveal signs of injury. Although the clinical picture was that of cerebral compression from subcranial hemorrhage and not that of diabetic coma, the possible presence of the latter condition could not be excluded. During the next five hours the pulse rose to 70 and the temperature to 101° F. It was then concluded to trephine over the left meningeal artery. No trace of fracture was found. A large clot was found and removed. This measured six fluid ounces. All hemorrhage ceased, a drainage tube was introduced and the wound closed. Six hours after operation, consciousness returned. The urine showed sp. gr. 1016, and was free from sugar. Nine days after operation, while the patient was straining at stool, a profuse hemorrhage took place. This ceased spontaneously. The next morning the hemorrhage recurred. Plugging with iodoform gauze failed to check it. The opening previously made was enlarged downward with the hope of reaching its source, but this failed. Nothing remained but compression or ligation of the carotid. Compression was precluded by the restlessness of the patient. The common carotid was therefore ligated. On account of the urgency of the case proper precautions looking toward asepticism could not be taken. The hemorrhage at once ceased. Suppuration occurred in both wounds. On the fifth day embolic pneumonia developed, but in four days this subsided. On the fifteenth day hemorrhage supervened from the carotid at the point of ligature. The bleeding came for the most part from the distal portion of the vessel. This was caught with great difficulty. The hemorrhage was checked, but the patient, who had lost consciousness soon after the artery gave way, failed to rally and died ten hours after all bleeding had ceased. A post mortem examination could not be obtained.

Officers for Ensuing Year: President—Dr. Claudius H. Mastin, Mobile; *Vice-Presidents*—Dr. J. Collins Warren, Boston and Dr. Stephen Smith, New York; *Secretary*—Dr. J. R. Weist, Richmond, Ind.; *Treasurer*—Dr. P. S. Conner, Cincinnati; *Recorder*—Dr. J. Ewing Mears, Philadelphia; *Member of Council*—Dr. Stephen H. Weeks of Portland Me.; *Chairman Committee Arrangement*—Dr. John S. Billings, Surgeon U. S. A.

The next meeting of the association will be held in Washington, D. C., in connection with the Congress of American Physicians and Surgeons, September 22, 23, 24, and 25, 1891.

Third Day, Thursday, May 15th—Morning Session.

Nephrorrhaphy was the subject of a paper by Dr. W. W. Keen, Professor of Surgery in Jefferson Medical College, Philadelphia, Pa. Mobility of the kidney exists in two varieties: First, movable kidney, and second, floating kidney.

A floating kidney has a mesonephron, and lies within the peritoneal cavity. A movable kidney lies posterior to the peritoneum, but may have quite as large a range of motion clinically as a floating kidney. It is distinguished anatomically, but it cannot be distinguished clinically. Unfortunately, movable kidney is generally overlooked, though quite frequent. For example, Shorszewsky found it to exist in 32 women out of 1,032 cases, and in 3 men out of 392.

Drummond has recently reported thirty cases observed by himself and Oser, of Vienna, and calculates that ten per cent. of mothers have this affection. It is more frequent in women than in men in the proportion of seven to one (Neumann, Landau), and is more than ten times as frequent upon the right side as upon the left.

Causes.—Floating kidney is always congenital. Neumann and Morris both cite undoubted instances. Movable kidney is commonly acquired as a result of a fall, blow, or any other traumatism, and not uncommonly from either frequent pregnancies or loss of fat.

Symptoms.—The diversity of opinion as to the desirability of operation varies with the appreciation of the symptoms. Thus, Landau thinks that operation is never justifiable; whereas Kepler advises immediate nephrectomy. Tait has operated upon but three cases, and he declares that he "will never have anything to do with fixation of the kidney." But the discomforts arising from movable kidney are many and decided, such as bearing down or dragging pain in the loins; gastric disturbances; fetid breath; vomiting, and, not uncommonly, marked cardiac symptoms. In women the disturbance of menstruation and various pains in the generative organs are very common. Besides discomfort, however, there is serious danger to life if the affection is not remedied.

Berry records cases of death six weeks after the diagnosis was made, and attributes it to rupture of an abscess of the kidney or of the urethra.

Neumann records 4 cases of intermittent hydro-nephrosis out of 21 observed by him, and in 5 albumin was present.

Kohler, Thornton, and others also record cases of hydronephrosis. A recent case of nephrectomy done by the author was necessitated by hydronephrosis following movable kidney.

The diagnosis is in general fairly clear. A movable tumor in the flank, of the size and shape of a kidney, which can be displaced to the iliac fossa, pushed back into the loin, and displaced to, or beyond, the middle line is indicative of the condition. A gall-bladder has in three instances been mistaken for a movable kidney. Percussion of the loin assists, but is less reliable than resistance to bimanual examination.

Sometimes the hilum can be made out, and the pulsating renal artery felt. The urine is generally normal, though it may contain albumin.

Treatment.—Treatment may be threefold. 1. By pad and bandage. This should always be tried first. 2. Nephrectomy. This is only occasionally justifiable. Its mortality is from twenty to thirty per cent. The mortality of nephrorrhaphy is only about two per cent. 3. Nephrorrhaphy. This was introduced into surgery by Hahn in 1881. The incision is made obliquely between the last rib and the crest of the ilium, beginning over the outer border of the quadratus, the perinephric fat being cut or torn through. Either the kidney or the liver may

be seen at once. The kidney may be so far away from its normal position that it will be necessary for an assistant to push it back. Mobility will not distinguish between the kidney and the liver, for a movable kidney will be as much affected by respiration as the liver.

One case was given by the author in which unintentionally the peritoneum was opened, as has been done by Hahn and others, in searching for the kidney. In order to distinguish between the two organs, the author advises that the upper border be sought for by the finger, as soon as the fat is torn through. If it be the kidney, the finger will readily reach its upper border, and be in contact with it behind the peritoneum. But if it be the liver, the upper border would be within the peritoneum and beyond reach.

In a second case the author had difficulty in getting hold of the kidney until it was harpooned by a tenaculum and drawn up into the opening and then seized with a volsella.

Traction with a volsella, even to such an extent as to tear through the kidney substance, has not produced any ill effects.

Four methods of fixation have been recommended. 1. By passing the stitches through the fatty envelope of the kidney. This method is regarded as insufficient. 2. By stitching through the fibrous capsule of the kidney. 3. By passing the stitches through the parenchyma of the kidney. Only occasionally has any blood been found in the urine. 4. Splitting and stripping back the capsule to obtain cicatricial union between the raw kidney substance directly to the surrounding tissues. The stitches are passed through the parenchyma where still covered by the fibrous capsule. Only four cases have been operated upon by this method, a number as yet insufficient to form a judgment as to its merits.

The third method has given the author very good results. The kidney seems to tolerate the presence of sutures for a long time without trouble, but whether in the degenerative changes of old age, or when the general health fails, they may become a source of trouble, time has not yet shown. The author condemns the stitching of the kidney to the ribs on account of its dangers. Both extremities of the kidney should be secured by sutures, with four additional sutures, two passing through the anterior and posterior lips of the wound respectively, and penetrating the kidney substance. The material that the author selects is fine silk, and he advocates that the stitches should be left in place. He recommends that the external wound be not sutured, as it closes quickly.

In the after-treatment he lays stress on keeping the patient in bed for not less than a month, and when she begins to go about, that a snug-fitting elastic bandage be worn.

The paper is accompanied with a table of all the recorded cases, one hundred and twenty-eight in number.

Four deaths have occurred. One not due to the operation, but to ileus. A second was fatal from inflammation of the pleura, due to stitching the kidney to the twelfth rib. In the third, death was caused by passing the stitches through an old embolic infarct, resulting in septicæmia; and a fourth, from later suppuration, probably the result of the operation.

The author has done four cases. The first has been published in the "Transactions of the Philadelphia County Medical Society," vol. x., 1889. For over a year the patient has continued in excellent health.

The second case, Mrs. M——, was operated upon October 16, 1889. She had suffered from great pain, gastric disturbances, dragging in the loin, and was rendered almost a permanent invalid. From childhood she had "had a queer feeling, as if she was not all right in the right loin," and two years prior to the operation she had a severe fall off a step-ladder.

At the operation the kidney slipped from the grasp of an assistant who was pushing it back in place. After tearing through the perinephric fat, what was thought to be the kidney pushed into place by the assistant proved to be the liver, and it was found that the peritoneum had been opened. The kidney could just be touched by the finger, and lay in the right iliac fossa. Harpooning it with a tenaculum, it was drawn into place and fastened by six silk sutures. It so completely closed the small opening in the peritoneum that it was not deemed necessary to close it by sutures. No ill effects followed, except considerable pain in the right hip and groin, presumably from bruising of the ileo-hyogastric nerve.

She made an excellent recovery from the operation, and is at present in excellent health, so far as the kidney is concerned, but is still suffering from some neurotic disturbances. Her highest temperature was only a little above 100° F., and fell to the normal on the fourth day.

While recovering from the nephrorrhaphy Alexander's operation was done, in order to fix a displaced and retroverted uterus.

The third case, Miss T——, distinctly traced her mobile kidney to reaching upward for a bale of goods. She "felt something give away" in the right loin, and asserts that she heard a "distinct snap." For three years she had been an invalid. On turning to the left side the kidney fell with a thud to the left of the middle line; the hilum could not be distinctly made out, but the pulsation of the renal artery was felt.

The operation was done February 18, 1890, and was followed by an uninterrupted recovery, the highest temperature being 99.8° F.

The fourth case, Dr. G——, a physician in active practice. For two years he had been obliged to give up his work, as the slightest exertion caused the most intense pain in the right kidney. The urine showed albumin and tube-casts. The pain was so severe that he often required a grain of morphia hypodermatically at a time. During the attacks of pain he has often passed blood. The right kidney was exceedingly painful and tender.

The patient and his father, both physicians, as well as Dr. O. H. Allis, believed that calculus in the kidney was probably the cause of the trouble. An exploratory operation was done March 6, 1890, with the intention of removing the stone, if there were any, or of doing nephrectomy if the kidney were disorganized. The moment the kidney was discovered it was seen to be exceedingly movable; respiration moved it at least two inches. Both to touch and sight it was normal. No evidence of stone or pus could be felt from the exterior. The kidney was then incised into the pelvis, which cavity was thoroughly explored by the finger. Neither pus nor stone was discovered. The bleeding was free, but not alarming. The wound was packed with iodoform gauze, and healed by granulation. The temperature rose as high as 103° F., but fell to normal on the twelfth day. He was exceedingly weak, and at first it seemed very probable that he would die. Gradually, however, he bettered, and on the eighteenth day he sat up.

At the end of six weeks the wound had closed; the urine was clear, with neither albumin nor tube-casts, and he has entirely given up the use of morphine for a month, as his pains have all disappeared.

The case was notable on account of the great severity of the symptoms and the difficulty of diagnosis from calculus or pyelitis. The results seem to show that the trouble was purely due to movable kidney. The symptoms were so grave that it seemed improbable that they were due simply to floating kidney. They seemed to indicate serious organic disease and threatened a fatal termination.

Surgery of the Liver, a paper by Dr. L. McLane Tiffany, of Baltimore, Md., was read by title. The following conclusions were presented: 1. The surgery of the liver is to be considered, as is the surgery of the rest of the body, not as surgery apart from everything else. 2. The liver may be cut, portions of it excised, tumors removed, bleeding arrested, and probably the flow of bile stopped by means at present in the hands of the surgeon. 3. Inas-

much as the liver is an abdominal organ, rigid cleanliness must be observed lest peritoneal inflammation follow. 4. The portion of the liver subjected to operation should be shut off as soon as possible, by suture or other methods, from the general peritoneal cavity, and healing induced by appropriate treatment.

The following papers were read by title: "Hypertrophy of the Prostate," by Dr. John A. Comingor, of Indianapolis, Ind.; "Lupus of the Tongue," and "Removal of a Retro-Pharyngeal Sarcoma by External Incision in the Neck," by Dr. David W. Cheever, of Boston, Mass.

The following resolution was presented and adopted:

"*Whereas*, In the treatment of fractures of the shaft of the femur the question often arises as to what is a satisfactory result in a given case; therefore,

"*Resolved*, That a committee be appointed by the President, to report at the next meeting of the Association, what, in their judgment, under the methods of treatment now employed, should be considered as satisfactory results."

The following committee was appointed: Drs. Stephen Smith, of New York; D. Hayes Agnew, of Philadelphia; David W. Cheever, of Boston; D. W. Yandell, of Louisville; Charles T. Parkes, of Chicago; P. S. Conner, of Cincinnati; C. B. Nancrede, of Ann Arbor, and Hunter McGuire, of Richmond, Va.

The following were elected to fellowship: Dr. A. Gerster, of New York; Dr. Robert Abbe, of New York; Dr. E. H. Bradford, of Boston; Dr. Oscar H. Allis, of Philadelphia; and to Honorary Fellowship, Professor Victor Horsley, of London.

The Association then adjourned, to meet September 22, 1891.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

TUBERCULAR ULCERATION OF THE BLADDER SUCCESSFULLY TREATED BY SCRAPING—AN ANOMALOUS CASE OF GASTRIC ULCER—DISCUSSION ON PYLORECTOMY AT THE MEDICAL SOCIETY OF LONDON.

LONDON, May 3, 1890.

THE tubercular affections of various organs seem to become more amenable to medical and surgical treatment, especially the latter. At the last meeting of the Clinical Society a remarkable case of tubercular ulceration of the bladder was narrated by Mr. W. H. Battle. The patient was a girl of twenty, who had suffered for ten months from frequent micturition; micturition was preceded by pain, which, however, did not accompany or follow the act. The urine was thick, and contained blood occasionally. The symptoms had gradually increased in severity, and when admitted into hospital the patient was obliged to pass urine every hour and a half or two hours, and had difficulty in retaining it; the urine was alkaline, sp. gr. 1.015, contained many pus and epithelial cells, and (occasionally) a trace of blood. The patient's mother had died from phthisis. The patient was examined under anæsthesia—the urethra being dilated—and an ulcerated surface was felt at the base of the bladder, about two inches in width by one and a half inch from above downward. This was rubbed with small sponges on forceps. Next day there was no pain. Cod-liver oil was given internally, and the bladder washed out twice a day with boracic solution. This was changed in thirty days' time for an acid quinine injection, there being but little improvement in the bladder symptoms, although there was less pus in the urine. The patient, however, was stronger and increasing in weight. A week later, she was examined again under ether and the cystoscope employed. The ulcer was found to be almost as extensive as on the former occasion; it was lightly scraped with the finger-nail and Volkmann's spoons, and sponges employed as before. Fifteen days afterward the patient left the hospital weighing fourteen and a half pounds more than on admission. Two months later she was readmitted. Injections—first of iodoform, and subsequently of balsam of Peru—were then used without any apparent benefit. A month afterward suprapubic cystotomy was performed. The rectal bag was employed, and the bladder injected with five ounces of warm boracic solution. The ulcerated surface in the bladder was exposed and scraped with a sharp spoon. After the scraping, a solution of chloride of zinc (thirty grains to the ounce) was dabbed over the surface. A self-retaining catheter was then passed into the bladder through the urethra, and a drainage-tube through the lower part of the wound. The upper part of the wound was closed with a silk suture and iodoform, and sal alembroth dressings applied. The urine was clearer by the fifth day, and the drainage-tube was removed. Six weeks later the patient could retain her urine for from one and one-half to two and one-half hours, and had no pain or discomfort; she left the hospital on the fifty-third day after the operation. She was now in good health, and able to hold her water for three hours. The tissue removed at the time of the operation was found to consist of tubercular material undergoing caseous degeneration. No bacilli were found, nor were any ever detected in the urine. It was suggested that the lesion was a primary one, not secondary to kidney disease. Primary tuberculosis of the bladder was rare, and the symptoms resembled those met with in some early forms of renal tuberculosis. Mr. Battle remarked that Guyon and Reverdin had treated the condition by scraping, and then touching the base of the ulcer with the thermo-cautery.

Some discussion followed the reading of Mr. Battle's paper. The President (Mr. Christopher Heath) asked whether Mr. Battle had been able to do more by his operation than could be accomplished through the dilated urethra. Mr. Raymond Johnson referred to a phthisical patient in whom a vesical ulcer had been much benefited by the use of iodoform emulsions. Mr. Harry Fenwick thought the diagnosis was imperfect, as no bacilli were found, and he did not think it possible to diagnose tubercular from scrofulous ulcers by the cystoscope alone. He also thought that, with a female patient, a surgeon could, by dilating the urethra, treat the ulcer by local applications. He used lactic acid for this purpose, and found the ulcers heal in the course of a few months; he mopped a five per cent. solution on to the ulcer, or injected a one per cent. solution into the bladder. Mr. Battle replied that he had only resorted to cystotomy after other milder methods of treatment had failed.

At the same meeting of the society, Mr. Barton read an account of a case of gastric ulcer in which symptoms of perforation occurred, followed by peritonitis. Improvement gradually took place, however, but a purulent discharge came away from the bowel, and on one occasion a quantity of horribly fetid gas was discharged by the mouth. The author thought that an abscess had formed after perforation, and that it had communicated with the colon. The patient recovered.

Pylorectomy constituted the subject of discussion at the last meeting of the Medical Society. Sir William Stokes, of Dublin, read a paper in which he narrated the history of the case, on which he had himself operated, and, after briefly referring to five other published operations, proceeded to discuss the general question, and especially in reference to the causes of the operation having been so unsuccessful in this country; only one successful case (Mr. Rawdon's) had been published, and that quite recently. Sir William Stokes considered that one great cause which had militated against success was the late period in the development of the disease at which the operation had been, as a rule, undertaken; hence he urged that in all doubtful cases exploratory measures should be adopted with the view of determining the nature of the disease, the existence or non-existence of adhesions,

and the presence or absence of much glandular infiltration. He regarded washing out or irrigation of the stomach as a desirable antiseptic precaution, and one which could be easily carried out without exhausting the patient. The protracted nature of the operation—as usually performed—was an important element affecting the result, as shock and ultimate collapse was thus likely to be induced. The operation could be shortened by abandoning the use of so many and such complicated sutures. The author said he felt confident that an efficient closure could be made by confining ourselves to the serous and muscular structures, and letting the mucosa take care of itself. Time would also be saved by the employment of the continuous suture—at all events in the curtailment of the pyloric end of the stomach. Another plan would be the employment of Senn's decalcified bone plates. He did not consider that the history of the operation should lead to its disuse.

The President (Mr. Knowsley Thornton) said he could not agree with the author that one could even rely upon obtaining perfect asepsis in these operations. He doubted whether the mere duration of the operation was to be credited with any great effect in determining the mortality. He thought much of the non-success was due to the fact of the operation being performed for malignant disease. He remarked that malignant disease within the peritoneum was characterized by a disposition to early diffusion, and this fact must necessarily militate against the ultimate success of the operation.

Sir William MacCormac urged that in the cases hitherto recorded the operation had been undertaken at a stage of the disease when the chances of successful intervention were reduced to a minimum. He could not conceive of the operation ever proving a success unless carried out at a time when the patient was far too well to induce him to submit to it.

Mr. Bryant pointed out that the effect of an exploratory operation was to aggravate malignant disease; apart from this fact, the wisdom of performing one at an early period could not be questioned.

Mr. Bowreman Jessett said he was the first surgeon in this country to put Senn's proposals to the test, and the results of his observations had been to fully convince him of the correctness of Senn's views.

Mr. Pearce Gould remarked that there were no symptoms in the early stage of malignant disease of the pylorus or until obstruction was caused, so that even the exploratory operation would not be of much use. Moreover, cancer of the pylorus usually proved fatal by causing obstruction; they had, therefore, to consider what was best to relieve the obstruction, and he thought gastro-enterostomy would be found the easier and safer operation.

Dr Giebart Smith mentioned a case in which pyloric obstruction had been found to be due to ulceration on the duodenal side of the pylorus; since that case he had seen several cases of sudden pyloric obstruction probably not cancerous in nature.

Mr. Barker observed that there must be something very wrong either in the diagnosis or treatment of these cases to have entailed such unfavorable results, seeing that in the hands of German surgeons nine operations for gastrostomy out of thirteen had proved successful.

Sir William Stokes, in replying, said he did not agree with Mr. Gould that there were no symptoms in the early stages of pyloric disease, for the existence of stenosis rendered the diagnosis possible. He thought that when the disease was too extensive to admit of the affected parts being removed *in toto*, then gastro-enterostomy might prolong life for a time, but the fact that the diseased tissues were left behind after an operation of such magnitude would have to be borne in mind.

A New Hospital, with a capacity of twenty-six beds, was recently opened near Bridgeport, Conn. It is in connection with the Soldiers' Home at Noroton.

OUTRAGEOUS QUESTIONS IN TAKING THE CENSUS.

To the Editor of the Medical Record.

Sir: Having read, with profound regret, the very able and strong letter of Dr. H. B. Millard in your issue of May 17th, that the following questions are the law of the land, to be asked by officers legally appointed, and to be answered by the PEOPLE:

"Whether suffering from acute or chronic disease, with name of disease and length of time afflicted?

"Whether defective in mind, sight, hearing, or speech; or whether crippled, maimed, or deformed, with name of defect?"

To ask such questions in ten millions of American homes, is too gross to contemplate; refinement, propriety, modesty, decency, every sentiment of mind and heart revolts at the bare suggestion—the cold, heartless, unsympathetic, and unprofessional census-taker, to be told at the hearthstone and family altar that the wife has chronic —— and the daughter acute- —— ! ! !

What were the men who framed these questions thinking about? Did they not hear from the shores of the Atlantic Ocean to the tops of the Rocky Mountains, and from these mountains to the shores of the Peaceful Sea, from every hill and valley in this great land, the echo answering no! no! no! The value of the census depends upon "facts" ascertained by the "truth"; there would be little truth and few facts in answer to these remarkable questions.

It is to be hoped that the journals and medical societies will at once step to the front and stop at the fountain-head, if possible, the attempt to perpetrate this great wrong; the wrong will never be accomplished; the attempt will annoy, worry, harass, not only the well and strong, but those suffering from acute and chronic diseases, afflicted with defects in mind, sight, hearing, and speech, the crippled, maimed, and deformed.

For more than two centuries the writer's forefathers have been citizens of Maryland; nearly every generation in the legislature they have assisted in framing the laws, by word of mouth, tradition, reading, and study; he has been taught that it was a great principle of American law, derived from the English law as expounded by Coke, "For a man's house is his castle," as quoted by Dr. Millard. Again Blackstone says: "Anything that is contrary to reason and common sense is contrary to the common law." He sleeps with his fathers, his words and thoughts of a past century are to-day burning in the minds and mouths of students, lawyers, and statesmen.

In no spirit of levity, the writer suggests, he has been taught that the Constitution of the United States forbids cruel and unusual punishments, and respectfully submits that no more cruel and unusual punishment could be inflicted by our laws upon innocent people, than in many cases the truth about the private infirmities of the daughter, the mother, the wife. Respectfully,

J. M. WORTHINGTON, M.D.

ANNAPOLIS, MD.

FEMALE PHYSICIANS FOR THE INSANE.

To the Editor of the Medical Record.

Sir: In the MEDICAL RECORD of May 3d there is a criticism of the act recently passed by the Legislature: "To provide for the employment of a woman physician in State Hospitals and Asylums," which is not marked by the fairness of statement and liberality of spirit we usually expect from the MEDICAL RECORD.

The act in question provides that in each such State institution, the physician-in-chief shall appoint, in addition to his present assistants, a competent woman physician as a resident assistant, "to perform such medical duties in and about the care of the women insane, as such superintendent or chief medical officer shall direct." There are at present six institutions to which this act

would apply. These, last year, treated three thousand four hundred and seven insane women, and not quite so many men. The six superintendents had under their direction twenty-six assistants. This act would add six women resident physicians, to do such part of the care of these three thousand four hundred women as the superintendent may allot to them. This can hardly be fairly described as "to compel them to employ female physicians for the female wards."

The superintendent is free to employ his male assistants in the care of these wards, and to limit the work of his female assistants as he sees fit.

As to the difficulty of filling six places with a salary of $1,200, there would probably be applicants enough; and the superintendent is free to require the same tests of fitness that he demands of his present assistants, while he can limit the duties of his woman assistant to what she can perform efficiently.

It would seem self-evident that among three thousand four hundred women insane, there must be many cases in which the attendance of a woman would be eminently suitable, and that of a man, especially of a young man, eminently unsuitable.

Your critic thinks women unpopular with women as physicians, and thinks it "hardly fair to take advantage of their lunacy to impose one upon them by law." But what of the women who would prefer a woman attendant? Is there no hardship for them in the present arrangement? This act gives for the first time the power of choice, subject to the discretion of the chief.

No permission to employ a woman assistant, as suggested, was requisite. There was no obstacle to such an appointment before the act. In the Willard Asylum there has for some time been a resident woman assistant. The present act, adding women as additional assistants, was intended to obviate any objection to curtailing the positions for men, and also to give a more authoritative expression of public opinion.

For this act was not the work of women physicians. It was not introduced for their benefit, nor with their knowledge. It is due to the strong feeling which has grown up in the lay element interested in these institutions, as to the impropriety of the system which takes advantage of their lunacy to impose exclusively male physicians upon insane women by law.

The act women physicians would ask for would be one to the effect that, wherever women are treated as patients in State or municipal institutions, there women should be eligible as physicians, upon the same terms as to qualifications, etc., as men.

We believe, some time, the MEDICAL RECORD, and other medical journals will acknowledge this claim to be simply justice to women, both as patients and as physicians.

AN OLD SUBSCRIBER.

THE FEES OF EMINENT MEDICAL MEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Observing in your last issue an item about the large fees obtained by Dr. Sexton, Dr. Parke, and other expert medical counsellors in this country, it occurs to me that your readers may be interested in the following sketch of a successful English physician from the pen of a layman in the *Pall Mall Gazette*.

"SIR WILLIAM GULL.

"Sir William Gull was one of the ablest, most original, and striking personalities which a somewhat conventional profession has produced in this generation. Everything about him was picturesque; his humble origin as son of a village trader; his Napoleonic cast of face and feature; his brilliant conversation, teeming with epigrams, paradoxes, and quotations; his extreme simplicity of life at home, and his influence and reputation at court and in 'society' combined to make him one of the most notable and enigmatical personages of the day. A small adventure, which by a mere chance interview as a boy-guide introduced him to no less a person than the resident Governor of Guy's Hospital, was the opening event of his great career. The Governor was struck by the beauty and intelligence of the boy, and his frank story of his love of reading, and he promised him a free education. From the Bluecoat School, where he was trained, he was translated by his patron to the gallipots of Guy's Hospital, and, beginning with the humblest offices of pharmacy, he rose by dint of talent and hard work to the highest summit of fashion as a physician, the friendship of princes, and all the honors which the ancient universities could pour upon him. From the first, those who knew him intimately predicted his brilliant career. Of a manly and massive type of comeliness, and with fascinating manners he knew how to combine the graces of the courtier with the sagacious profundity of manner which is one of the secrets of success in the difficult career of a court physician. He cultivated the art of conversation with as much assiduity as the subtle methods of bedside diagnosis and palatable prescriptions. As an orator he possessed rare gifts, and when Gull was to deliver an oration, either at the College of Physicians or at any of the more popular medical assemblies, there was sure to be a crowded attendance, and there was always something well worth hearing. He delighted in paradox and in piquant generalizations. He did not fear to shock his professional brethren by a well-matured and aggressive incredulity of the value of medicines. The great mistake of the poor, he once told a popular audience, is that they cannot be reasoned out of their belief that disease comes by Providence and goes by medicine. His mint-water treatment of rheumatism shook the foundations of many a well established system of medication, and the results which he achieved by the adoption of what were at the time considered almost Nihilist theories of therapeutics made his wards in Guy's Hospital for the time more famous than popular.

"To those old-school practitioners who ticket every symptom and have a dozen drugs for every disease which they can label, Gull was a type of disappointment and despair, but even they had to acknowledge that he understood the man better than they could treat the disease, and that his patients worshipped him, and had a happy knack of recovering without swallowing all the time-honored doses of the Pharmacopœia. Many are the stories of his cleverness in disconcerting inquisitive patients by brilliantly ambiguous answers. To one great lady who was determined to gather from him what was the nature of the fatal illness of a patient as to which he was not willing to be too precise, he replied, 'Madam, she is dying of cachexia,' with which she was perfectly satisfied. He was an elaborate note-taker, and was wont to refresh his memory with notes of the past consultations before each patient was introduced into the room, so that old patients, and with justice, were delighted with the accuracy with which he recalled their histories and symptoms, and were sometimes wont to set this down to superhuman retentiveness of memory, and to an intense personal interest in their case, which sharpened their sense of surprise and gratitude. Great success, and the worship of all the duchesses, naturally translated itself into one of the largest contemporary professional incomes, and Sir William Gull acquired great wealth; but it might have been much greater but for his large generosity in refusing fees from those who could ill afford to pay them, and for the moderation of his demands where superfluous liberality would readily have increased his moderate fees. He was devoted to his hospital work, and would visit his wards late at night whenever an anxious case demanded his presence. He was idolized by the students, who delighted in his lucid diagnoses, his incisive teaching, and his philosophic generalizations. He was the friend of many a poor philosopher and struggling scientist. In thought he was a pupil of Spinoza and a friend of Hinton,

whom he did much to bring forward into fame and professional fortune, and to whose life he has written a touching and sympathetic introduction. Seldom has a court physician, well versed in the minor arts of life, shown so wide and catholic a love of science and philosophy for their own sake; seldom has a man been able to combine such brilliant material success with simplicity of life and devotion throughout a busy career to the higher forms of mental culture."

Sir William Gull was for many years a most popular consultant, and from one hundred to two hundred and fifty guineas for running down from London to Liverpool and other places, was not an unusual fee for his services. Of course, one thousand dollars a day seems a princely sum to receive, but the inconveniences attendant on a sudden journey are great, and the loss sustained by many days' interruption of business is often scarcely covered by these seemingly high fees. It would be a great mistake to conclude, because wealthy persons reward the consultant in so liberal a manner, that patients of lesser means are neglected; indeed, it will generally be found that an immense amount of professional work is done by eminent medical men without any pecuniary remuneration.

Chicago, Ill., May 22, 1890.

THE BELLIGERENT BACILLUS AND THE WAR OF EXTERMINATION.

To the Editor of the Medical Record.

Sir: In the very comprehensive report of the proceedings of the meeting of the New York County Association, published in your issue of May 3d, there is an unintentional injustice done me by the reporter, who credits me with "expressing myself as more disposed to trust in nature."

Trusting in nature is eminently proper while nature is doing the work safely and well; but when, for any reason, those efforts are inefficient and unavailing, the time is at hand for intelligent assistance. To know when to give assistance, and how to aid nature, marks the difference between "granny's" help and that of the skilful accoucheur.

The writer intended to be understood as favorable to Credé's method, and endorsing what the author of the paper said in its favor.

The doctor, however, severely criticised traction on the cord, even though it was slight, as well as the introduction of the finger or hand for the purpose of aiding in the completion of the third stage. It is not a strained inference to say that there were no exceptions hinted at in the paper. Believing this to be unintentional, and to ascertain his views as to possible complications, the questions were asked: Is Credé's method always successful; was there such complications as "hour glass contraction," "adherent placenta," extreme uterine inertia, and, finally, central descent (as when the placenta is drawn down by a short cord during labor) forming a button-hole or suction obstruction?

In closing the discussion, the doctor answered the questions in part by stating: Credé's method, intelligently carried out, rendered those complications exceedingly rare. "Personally he could succeed in expressing the placenta during the course of three or four uterine contractions in ninety-nine cases out of a hundred. Where there was adherent placenta, and expression could not be effected in three or four pains, he would not hesitate to pass up his hand and remove it. He would, however, first thoroughly disinfect his hands with bichloride."

The point gained, then, by the question was, the admission that, in exceptional instances, Credé's method would fail. In these exceptional cases (at least one in a hundred, and, if not so skilful as the doctor with the method, there may be two in a hundred) we have permission or authority to introduce the fingers or hand, and complete the delivery of the placenta.

The above reference to cleansing the hands with bichloride solution, was a criticism on the casual remark of the writer, that soap and water was deemed satisfactory and sufficient.

The criticism was just and deserved, and the only excuse to offer is the difficulty in keeping track of the numberless "cockeyes," and the inconsistencies of the deductions of some of the theorists.

It is not ancient history when we were all using carbolic acid, and when they discovered that the bugs got fat and danced in the solutions we were using; then bichloride was, and is the fad, in spite of the alleged discovery that, in any strength we dare make use of, the germs prospered.

The great Yankee nation was not to be balked in that way. If the disinfecting solutions would not destroy the unruly cockeyes in the human economy, "Why, keep 'em out," cried one of our eminent and inventive gynecologists, and proceeded forthwith to invent a trap-door and, eureka! he had them. He called his invention an antiseptic pad. It allows of egress, but not of ingress. If the germs got out for a little fresh air, there was no return coupon; and by simply extending it—connecting the different pads with straps or ribbons—you had a "buck-fence" that shut them out of the anus, vagina, and umbilicus.

This apparatus will be of great advantage to the small boy, as it is easier of application than doing him up in antiseptic gauze before going in bathing; and since we have learned that the North River is chock-full of the "small bacilli" which are the cause of pink-eye, it will be necessary to take some precaution.

A large pad might be used at the Battery as a dam, and then the river might be disinfected with bichloride. It would not hurt the North River.

Daniel Brown, M.D.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 24, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	1
Scarlet fever	76	6
Cerebro-spinal meningitis	4	4
Measles	410	30
Diphtheria	113	26
Small-pox	0	0
Varicella	3	0
Pertussis	1	0

Surgical Geniuses.—Professor Hebra, of Vienna, used often to express himself in this wise: "It is necessary that there should be surgical geniuses, but don't ever let a surgical genius operate on you."

How to Prepare Sponges for Surgical Use.—Head Nurse Miriam Coogan, of the Gynecological Ward, Johns Hopkins Hospital, in the *Nightingale* for March 29, 1890, describes the process of preparing sea-sponges for use in her ward, as follows: 1. Beat well in muslin bag to remove sand. 2. Immerse in solution of muriatic acid, one ounce, to water one pint, for three hours to dissolve remainder of sand. 3. Keep for eight hours in hot running water. 4. Immerse in bichloride of mercury, 1 to 1,000, for ten hours. 5. Preserve in four per cent carbolic solution. Occasionally I bleach them by soaking for half an hour in a solution of permanganate of potassium, 1 to 20, afterward washing in pure water, then in saturated solution of oxalic acid. This is merely for æsthetic effect, and, as our sponges are never used twice, I seldom go beyond cleansing and disinfecting.

ON CONICAL STUMP AFTER AMPUTATION IN CHILDREN, WITH ESPECIAL REFERENCE TO ITS PHYSIOLOGICAL CAUSES AND PROGNOSIS.[1]

BY CHARLES A. POWERS, M.D.,

SURGEON TO OUT-PATIENTS, NEW YORK HOSPITAL; ASSISTANT SURGEON TO THE NEW YORK CANCER HOSPITAL.

IN September, 1883, while I was serving on the house staff of the Chambers Street Hospital, the following case was admitted to the institution:

G. H——, a boy, eight years of age, who had suffered amputation of the right arm, in its upper third, four years previously, presented himself with a conical stump at the seat of the primary amputation.

The end of the bone was covered only by skin, and this was adherent, tightly stretched, and showed commencing ulceration. The tissues were divided at the end of the stump, scraped back from the shaft, and two inches of bone removed by the saw. The wound was healed at the end of twenty days, and the patient was discharged. Reference to the history-books of the hospital showed that at the time of the original amputation the stump was well covered.

The boy is now fifteen years of age, and present examination shows that there is an osseous "teat" projecting from the middle of the end of the humerus. This teat is about one-half of an inch long and is shaped like a mammary nipple. The skin is adherent at its base on its upper and inner side. The old cicatrix is on the outer side of the stump. It is serpentine in shape, its upper extremity being two inches above the end of the bone.

The present condition is shown in Fig. 1.

FIG. 1.—Primary amputation in 1873. Re-amputation in 1883. This cut shows appearance of stump, March, 1890.

In November, 1886, I saw, in the clinic of Dr. W. T. Bull, at the New York Hospital, a boy, aged six, whose arm was to be re-amputated for conical stump. The primary amputation, through the upper third of the arm, had been done four years previously, and the resulting stump was typically well covered.

Two years after the original amputation, owing to growth in the humerus, the stump was conical, and bone to the extent of two inches was taken from its end.

Two years after this first re-amputation the stump was again conical, the end of the humerus projecting through the cicatrix and giving rise to much pain and trouble. One and one-half inches were taken from the end of the bone at this second re-amputation.

Fig. 2 shows the appearance which the stump presented at that time.

This boy was again in the New York Hospital in April,

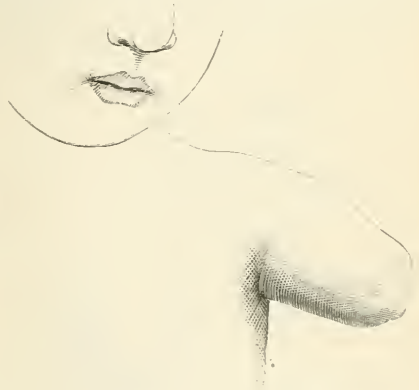

FIG. 2.—W. W——. Primary amputation in 1882. First re-amputation in 1884. This cut shows appearance of stump at the time of the second re-amputation, 1886.

1889, and I quote from his history in the hospital case-book: "The end of the bone is covered only by skin, and this is very tense and adherent. It is ulcerated over an area the size of a dime. The adjacent soft parts are painful and tender. An incision three-fourths of an inch long was made over the projecting end of the humerus, the skin reflected back, and the tissues cut away from the bone; one inch of the humerus was removed."

I present this boy to you now. It is one year since his last operation. The end of the bone is pressing well against the skin, yet that tissue is supple and non-adherent. Remember, if you please, that four and one-half inches of bone have been removed from his humerus since the original amputation in 1882. His mother says: "Every two years the bone grows down and has to be cut off."

In Fig. 3 the present condition of the stump is shown.

In the summer of 1887 I saw a boy, aged fourteen, who had suffered amputation through the middle of the arm during my service as House Surgeon to the Chambers Street Hospital three years previously. The boy's stump was distinctly conical, the end of the bone pressing against the tightly stretched skin.

The cicatrix, which at the healing of the primary operation was at the lower part of a well padded stump, was now at some distance above the end of the bone. Resection of the bone was advised, but refused by the parents.

In January of the present year the following case came under my observation:

[1] Read before the Section on Surgery, New York Academy of Medicine, March 10, 1890.

M. S——, a boy, aged nine, was brought to me for examination, his condition being as follows: The stump of the right humerus, which bone had suffered amputation at the junction, approximately, of its upper fourth with its lower three-fourths, three years previously, was the seat of an extremely marked conical condition. The shaft of the bone was continuous below, with a long, narrow, tapering, osseous projection. This projection pressed strongly against the tightly stretched skin which was adherent over its end, and which at that point showed commencing ulceration.

Firm palpation discovered the projection to be continuous with the shaft of the humerus and in the line of its long axis.

At the postero-external aspect of the stump was a semilunar-shaped scar, its convexity being downward. Its centre was $\frac{1}{4}$ of an inch above the end of the bone; its anterior and posterior extremities were, respectively, $1\frac{3}{4}$ inches and $2\frac{3}{8}$ inches above the point of the projection.

This was evidently the amputation scar.

The soft parts in the immediate neighborhood of the end of the stump were inflamed and sensitive.

As has been stated, this patient's arm had been amputated three years previously. Two years previously—one year after the original operation—he was seen by me. At that time the condition of the stump was in every

Fig. 3.—W. W——. Appearance of stump one year after third re-amputation.

way good. The soft parts over its end were abundant and freely movable. The cicatrix was below the end of the bone; the stump was painless. The parents of the patient[1] say that they have seen the end of the bone grow down, little by little, during the past year and a half. They have seen it press against the soft parts, and have seen the skin adhere and become ulcerated.

The present condition of this patient's stump is shown in Figs. 4 and 5.

Observation of these four cases of markedly conical stump, occurring in young children who had suffered amputation through the arm, has led me to make such investigation as I have been capable of making, and to introduce the subject for your consideration, propounding this question: "Is an amputation through the upper part of the humerus of a child liable to be followed by the development of a conical stump; and if so, what special factors are concerned in the production of this untoward result?"

From a prognostic point of view the matter is certainly one of importance. If a conical stump, one demanding secondary operation, develop after an amputation, opprobrium may, perforce, attach to the surgeon who originally operated; while if such event is to be expected in natural order, a corresponding prognosis is, of course, to be made.

Again, viewed from a medico-legal stand point, importance must attach to the subject. If a child loses a limb in a railway accident and compensatory damages are to be awarded, the jury have a right to know whether or not a future operation, with its attendant pain and risk, is probable, and to take account of such probability in making their award.

In point of fact I have reason to know that such fac-

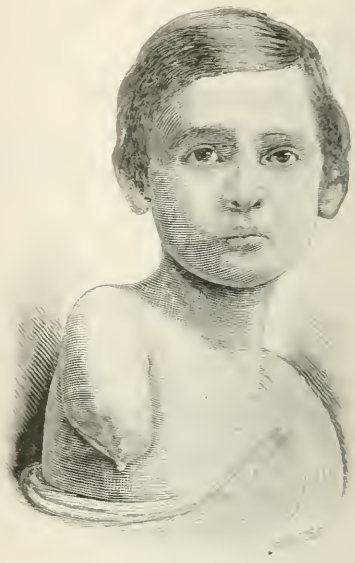

Fig. 4.—M. S——. Three years after amputation. Antero-external aspect of stump, March, 1890.

tors were brought up for consideration in the case of the last boy whom I have shown to you, and whose guardian brought suit against a railway company for the loss of the arm.

I have made diligent effort during the past week to investigate the remote results in all cases of amputation, in patients under twenty years of age, which occurred at the Chambers Street Hospital previous to the year 1888.

Fig. 5.—M. S——. Postero-external aspect of the stump shown in Fig. 4.

These cases were ten in number—three through the thigh, one through the forearm, and six through the arm. Of the thigh cases but one could be found, that one being a patient who, in 1877—he being then eleven years of age—had been amputated through the junction of the upper

[1] This patient and the two whose histories were first related were exhibited before the Section.

and middle thirds. He did not require subsequent operation, and the stump is at present in good condition. The patient whose forearm had been amputated could not be traced. Of the six arm cases all but one has been seen within a week, and that remaining one [1] is said to have died some years ago. Two of these cases developed "conicity," and their histories have been related. Each of the other three cases was in a boy who was fifteen years old at the time of the operation. Neither of these three has required a subsequent operation, though in each the bone has shown an increase in length which is very marked when compared with the growth in the soft parts.

In 1853 Denonvilliers [2] presented before the Société de Chirurgie of Paris a boy, aged seventeen, whose right arm had been amputated through its middle, ten and one-half years previously. Some time after the original operation a projection of bone was seen to be making its way into and through the flesh, and at the time at which Denonvilliers presented the patient there was a protruding necrosed point 3 ctm. in length.

At the same meeting Gueresant related the case of a young child whose arm he had amputated at the middle. Four years after the operation the patient presented a markedly conical stump, resembling that of the patient of Denonvilliers. The parents of the child said that they had seen this projection grow, little by little. Gueresant asked whether this condition was not due more to the physiological elongation of the bone than to the manner in which the original operation had been performed. Denonvilliers, however, thought faulty operation the more probable cause.

In 1859 Chassaignac [3] presented to the same Society a specimen of conical prolongation which he had removed from a femoral stump. Similar cases were related by Verneuil, Marjolin, Broca, and Bouvier, the latter asserting that elongation in the leg was due to the great growth which took place at the upper part of the tibia, and recommending that in amputations on children the flaps should be made of extraordinary length in order to make allowance for this natural elongation of bone. There was much difference of opinion among the members regarding the nature of the osseous projection.

As best I can learn, Verneuil [4] was the first to accurately describe the condition produced by elongation of the bone without inflammation and without retraction of the soft parts, and to this condition he has given the name of *conicité physiologique* of the stump. (I take the liberty of construing this literally, and make use of the word "conicity," as it seems to well express the condition described by the French writers.)

He says that it is seen principally in the arm and leg, because in these regions the superior epiphyses contribute so largely to the longitudinal growth of the bone. It is less often seen in the forearm and thigh, because of the lesser activity in the superior cartilages of the radius, ulna, and femur. He had seen a considerable number of such cases while distributing prothetic apparatus at the Central Bureau of the Parisian Hospitals, and he described in detail two cases which had occurred in his own practice.

This subject again engaged the attention of the Surgical Society of Paris in 1884, at which time Kirmisson [5] presented a boy, aged twenty, whose leg had been amputated sixteen years previously, and who, at that time, presented the following condition: At the centre of the stump there projected a long bony point 2 ctm. in circumference, separated by a transverse fissure into two tuberosities, of which the posterior was the longer and the larger.

It was difficult to determine which of these points belonged to the tibia and which to the fibula, but it seemed probable that both bones joined and fused. The skin over the end of this long bony projection was adherent and extremely sensitive.[1]

Kirmisson places treatment under two heads: First, prophylactic; second, the curing of the lesion when present in the stump.

Regarding prophylaxis he recommends the avoidance, when possible, of amputations in children; but when unavoidable, he advises that the flaps be made of extraordinary length, and that all possible means be employed to secure primary union in the wound.

Resection of the bony prolongation is to be employed for the relief of the conicity when that is present.

In the discussion which followed Kirmisson's paper, Farabœuf remarked that he had been surprised at finding that the growth of the skin had not been commensurate with that of the bone, and, without rejecting the theory of Verneuil, offered, as a possible explanation, the idea that when a stump is healed by primary union the deep parts, particularly the muscles, are not united as solidly as when the stump heals by granulation, and that as the ends of the muscles are left free they are able to retract, little by little, and to leave the end of the bone covered only by skin. Whatever the cause, he felt it wise, when amputating in children, to leave exceptionally long flaps.

Trélat believed, with Verneuil, that the conicity in children was due to elongation in the bone.

Berger spoke of a case which he had seen, in which an enormous hyperostosis had developed in a leg stump. He had found the morphological result to be the same as when the elongation was purely physiological.

Referring again to Farabœuf,[2] we find that at a later date he professes entire belief in the theory of elongation of the bone, saying that "when a young child is amputated just below the knee, both epiphyseal cartilages are left; they have been irritated by the operation, and may in years produce a growth of bone which is equal to one-half the length of the limb, while the soft parts grow only sufficiently for one-quarter of the member. Analogous processes may take place in other bones, but more especially in the arm. Farabœuf advises that flaps be made of such length that they may be ample for the bone in its future physiological development.

Schede refers to the French writers and agrees with their conclusions.

Mr. Bernard Pitts says:[3] "After amputation through the shaft of a single bone, such as the humerus or femur, the stump generally becomes a little conical in time, owing to atrophy of the soft parts.

"In young subjects, with active growth of the bone going on, this condition of stump is sometimes extreme, the end of the bone, covered by stretched skin or cicatricial tissue, projecting very much like the stick of a half-opened umbrella; and this may take place in a stump which was originally well formed."

T. Bryant says:[4] "At times, however, stumps grow and become conical, and in the amputations of childhood this condition must be expected. It is best seen in the leg, as it so happens that the shafts of bones grow most where they come in contact with the larger epiphyses, and in the leg the one entering into the knee-joint is the larger."

Spence[5] alludes to the growth of the bone after amputation in young persons, this growth giving rise to projection of the cicatrix and conical stump. His own observation led him to believe that the bone may continue to grow in the young, and thereby tend to produce conical stump.

He refers to a case of amputation of the upper arm

[1] Dr. F. W. Murray, formerly surgeon to the Out-patient Department of the Chambers Street Hospital, tells me that while on duty at the hospital he saw a young child whose arm had been amputated through its upper part, and who returned to the institution some years afterward with a stump so markedly conical that the bone protruded through the soft parts. As I can account for all other cases I believe it to have been this child.

[3] Ibid., t. ix., p. 450.

[4] Mémoires de Chirurgie, vol. ii., p. 830.

[5] Bulletin et Mémoires de la Société de Chirurgie, vol. x., p. 521.

[1] A number of the French observers relate cases in which this *saillie longue* was seen. They correspond very closely with the boy S——, whose stump is shown in Figs. 4 and 5. I am at a loss to know what determines the shape of the projection.

[2] Manuel opératoire, p. 129.

performed by Mr. Liston in which the bone projected in an extreme degree and terminated in a hook-like process.

The practical deduction is, that in performing amputation on the young we should leave rather a redundancy of soft parts, in order to obviate the effects of the osseous development.

Watson[1] says: "It has been supposed, in some cases, that a failure in the growth of the soft parts to keep pace with the development of the bones had occasioned conical stumps, but additional proof is required to establish this point."

Ashhurst[2] says: "Hypertrophy of the bone is observed in patients who have not attained their full growth, and principally in amputations of the leg and upper arm. Its occurrence in these, rather than other situations, is accounted for by the well-known fact that, owing to the direction taken by the nutritious arteries in the several bones, and the consequent period at which the epiphyses become united to the diaphyses, the chief growth in the lower extremity is from the epiphyses in proximity to the knee, while that of the upper extremity is from that of the wrist and shoulder. Hence amputation of the thigh and forearm remove the principal sources of growth for the portions of bone which remain, while amputation of the upper arm and leg leave these sources, and in a few years the bones of stumps in these situations may be too long for the soft parts which were originally ample for their covering. If any treatment is required in a case of this kind, resection of the overgrown bone is the only remedy likely to be of service."

[Since the preparation of this paper three additional cases of conical stump have come under my observation. One of these was in a child, the other two were in young adults. The first was a boy, aged twelve, whom Dr. J. A. Wyeth exhibited before the Surgical Section of the Academy of Medicine on the evening on which this paper was read. His right humerus was amputated through its upper third when he was four years of age; when he was eight years old his parents found the end of the humerus coming through the soft parts, and took him to Dr. Wyeth, who re-amputated the arm. In March of the present year the stump was again conical. The end of the bone was pointed, and pressed firmly against the skin, which was adherent and ulcerated over this point. The appearance of the stump corresponded closely with that of the boy M. S——, shown in Figs. 4 and 5. I am indebted to Dr. Wyeth for courteously placing his notes on the case at my disposal.

The second case was seen at the Roosevelt Hospital, in the service of Dr. Charles McBurney, who very kindly permits me to embody a description of it here.

The patient was a young man, aged twenty-three, whose left arm had been amputated through its upper third when he was eight years old. The resulting stump presented a freely movable flap of good length, and it remained in excellent condition for four or five years, at the end of which time he noticed a slowly increasing protrusion of bone, and the stump began to pass into the condition which was present when the patient came under Dr. McBurney's observation.

At this time, there was a nipple-like protrusion of bone at the lower end of the humerus; this projection was about one and one-quarter inches in length, symmetrical, and covered by a very thin and closely adherent layer of integument. There was a tender lump about the size of a hazel-nut lying in the soft tissues on the antero-internal aspect of the stump about two inches above its tip. This lump was movable and painful. A longitudinal incision was made over the tumor and it was dissected out. It proved to be a neuroma. A circular incision was made in the soft parts, about one and one-quarter inches above the tip of the stump, the parts dissected back, and two and one-eighth inches of bone removed. This portion of bone is a part of the shaft of the humerus, and longitudinal section through it shows the medullary canal to extend, undiminished in size, to its extreme end.

Fig. 6—from a flash-light photograph, taken by Dr. Sinclair Tousey, of the Roosevelt Hospital house staff—shows the conical stump before operation.

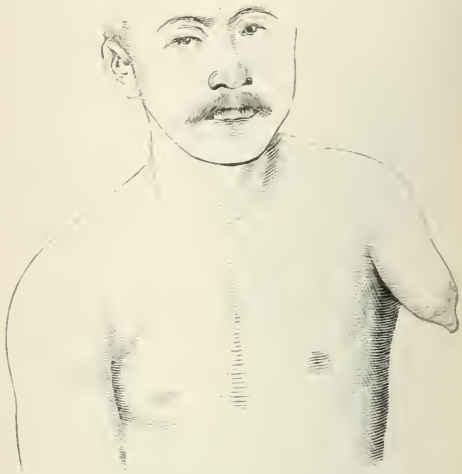

Fig. 6.—Patient twenty-three years of age. Amputation at the age of eight years.

In Fig. 7 the cut surfaces of the removed fragment are shown, the medullary canal being exposed.

The third case was shown by Dr. F. Tilden Brown, at a meeting of the Surgical Section of the Academy of Medicine, held on April 14th. The patient was a young woman, twenty-eight years of age, whose left leg had been amputated a little below the middle when she was six years old. When she fell under Dr. Brown's observation the stump was distinctly conical; it presented at its centre a long, tapering, bony projection, very similar to that shown in Dr. McBurney's case, though it was, I should think, rather more oblique. The skin was adherent over the end. The tibia, only, seemed to be involved.

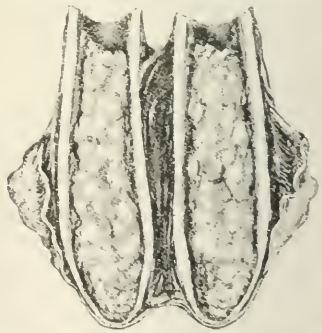

Fig. 7.—Section through bone removed from stump of patient shown in Fig. 6. The medullary canal is seen to extend to the end.

These last two cases were not in children, but they followed amputations on children and seem to bear directly on the theory of Verneuil to which previous reference has been made.]

I do not know that I can add anything in way of comment to the cases cited and the opinions quoted. The former comprise all of the cases[1] of amputation in young children of which I have been able to obtain personal knowledge, and it would seem highly improbable that the

[1] The majority of these were under the care of Dr. W. T. Bull, to whom I am under much obligation for permission to publish histories.

conicity in each of these is accidental, and that they are coincident. Certainly, no one can doubt that the long bones increase in length more by addition to their ends than by interstitial deposit. Take the humerus, for example. There the chief point of growth is at the upper end, where the epiphyseal centre is the first to appear and the last to become fused to the shaft. Here we have the constant ossification of the layers of cartilage ("Holden's Osteology") which intervene between the epiphysis and the shaft. These layers of cartilage constantly grow on the one surface while they ossify on the other.

Given an amputation through the humerus of a child, at a point not far below this epiphyseal line. The ossification of the cartilage is not interfered with, and increases the length of the fragment far out of proportion to the relation, in length, which the fragment itself bears to the original length of the bone. The growth in the soft parts is commensurate only with their length, and less in extent than normal because of atrophy and retraction.

Thus we may conceive that this constant osseous deposit in the epiphyseal cartilage tends to press the end of the bone into and through the soft parts.

The following propositions are submitted:

1. Amputation through the arm or leg in children may be followed by a conical condition of the stump, and this sequel is a probability rather than an improbability.

2. This conicity may be physiological, and independent of inflammation or retraction in the soft parts or of osteophytic deposit at the end of the bone.

3. The younger the child and the nearer the seat of the amputation to the upper epiphysis of the limb, the greater the probability of early conicity. These factors should be considered when making prognosis.

4. The weight of extant authority favors flaps of excessive length, but this measure may not prevent development of the conical condition.

5. When the conical condition is present, the only suitable treatment consists in the resection of a sufficient portion of bone.

6. Successive re-amputations may be required.

7. The above considerations may apply, but with very much less of force, to amputations through the forearm or thigh.

[The recorded cases of conical stump in children are few in number, and it would seem of value to gather all possible additional information.

I would, accordingly, request physicians who have observed amputations above the wrist or ankle, in patients under eighteen years of age, to kindly send me a brief note, stating the seat of the amputation and the ultimate condition of the stump.]

The Importation of Foreign Natural Mineral Waters.—At a meeting of the New York County Medical Association, held May 19, 1890, the following resolution was adopted: Resolved, That the New York County Medical Association, a representative body composed of five hundred practising physicians in the city of New York, believing that it is for the best interests of the people of the United States that all foreign natural mineral waters should be imported free of duty, respectfully urges upon the National Senate and House of Representatives that the provisions now in force relating to foreign natural mineral waters, and to the bottles in which they are imported, should be re-enacted in any tariff which is sanctioned by them.

Missions to Medical Students.—In London Gospel missions are given from time to time to medical students, and inducements in the way of abundant, if not particularly rich or dainty, refreshments are held out to them to attend the services.

THE ADVISABILITY OF WIRING RECENT SIMPLE FRACTURES OF THE PATELLA.

By WILLIAM F. FLUHRER, M.D.,

VISITING SURGEON TO BELLEVUE AND MOUNT SINAI HOSPITALS.

The operation of antiseptically opening the knee-joint in a recent simple fracture of the patella has now been done many times, often with brilliant success, but sometimes with less happy results. In this paper I propose, mainly from my own experience with the operation, to discuss the questioned advisability of its performance.

After much hesitancy I directed and supervised my House Surgeon in performing the two following operations:

Case I.—Wiring seventeen days after fracture, under continuous irrigation with boro-salicylic acid solution; infolded fibrous tissue upon the broken surfaces of the fragments; bony union with flexion to forty-five degrees for four and a half years, when, from accidental rupture of adhesions, full function of the joint was recovered.

G. G——, aged forty-two, harness-maker, was admitted into Bellevue Hospital, November 6, 1883.

The patient, while walking, fell, striking his right knee upon the curbstone. He was then unable to stand.

Upon admission the right knee was found contused, swollen, and tender. The patella was broken transversely through its middle, the fragments being separated about one-fourth of an inch; the limb was placed upon a posterior splint, and an ice-cap was applied to the knee.

November 15th a plaster-of-Paris splint was applied to the limb. The region of the knee-joint was exposed and the fragments held together by strips of cloth saturated with plaster of Paris, used according to the plan of the late Dr. J. L. Little.

Operation, November 23d.—The patient having consented to the wiring of his patella, the joint was opened, under irrigation with a solution of a mixture of boracic acid five grains, and salicylic one grain, to the ounce of water. At first a longitudinal incision five inches long was made, but this not giving sufficient room, a transverse incision was also made, completely opening the joint. A large clot between the patellar fragments was removed, the ruptured fibrous tissues over the patella, which had turned in over the fractured surfaces, leaving only a small margin of the bone exposed, were cut away, and the fragments, having been drilled, were held together by three wire sutures. On account of the long exposure of the joint, as an additional safeguard against infection, it was finally flushed with a five per cent. solution of carbolic acid. The joint was drained at the open ends of the transverse incision and by a catgut drain through the outer aspect and lowest point of the synovial pouch. The wound was closed with catgut sutures, but to avoid tension the thickened tissues were allowed to gape at the middle of the longitudinal incision. The wound was dressed antiseptically; an anterior plaster-of-Paris splint was applied, and the limb finally suspended. The patient rallied well from the anæsthesia and shock of the protracted operation, which had lasted about three hours.

December 7th.—The joint was exposed under irrigation, and the gaping portion of the longitudinal wound is granulating healthily. There is no swelling or inflammation. The transverse incision was healed by first intention. The catgut drain has been absorbed. The limb was redressed in the same manner as at first.

December 28th.—The wounds have all healed except a small granulating patch at the middle of the longitudinal incision. A plaster-of-Paris splint was applied.

December 29th.—The patient was allowed to leave his bed.

January 26th.—The plaster-of-Paris splint was removed, and passive motion and hot douching of the joint ordered to be practised daily.

March 31st.—The patient was discharged from the hospital, with bony union of the broken patella, but scarcely any motion in the joint.

The patient was reluctant to attempt moving the joint, but from reliable information it was learned that in June, 1886, he had the power of flexion through forty-five degrees, and that there had been no refracture of the bone. He at that time was able to work at his former occupation.

October 7, 1889.—Till about one year and a half ago he could flex the leg only to an angle of forty-five degrees. At that time, while walking along a narrow foot-path in the dark, he fell ten feet into a gravel pit, striking upon his feet and forcibly flexing both legs. He heard a cracking and tearing in the right knee-joint during the forced flexion. In spite of great pain he walked about a mile, observing that he could bend the knee with more freedom. The next morning the joint was very much swollen, but he went to work, walking by the aid of a cane. In three or four days the swelling subsided and the motion was then as perfect as it is now.

Upon examination there was found complete power of extension and flexion. There is a crucial scar over the patella, the central limb being adherent to the patella at its lower portion. The scar is very thin, and through it can be seen the two small wires inserted at the operation. The scar is bluish over them, and the danger of their ulcerating through upon slight injury seems so great that their removal is strongly advised. The upper and larger fragment, in its union with the lower one, shows that there was a slight displacement outward at the time of wiring. The patella is lengthened one-eighth of an inch. It has free lateral mobility. The right thigh is one-half an inch less in circumference than its fellow. The patient states that it has grown considerably since he recovered freer motion in the joint.

Case II.—Fracture of the left patella, in 1870, from direct violence; injury not recognized or treated; permanent crippling of the limb.

July, 1883, fracture of the right patella from direct violence; ligamentous union, with fair amount of function, in four months; five months after injury, rupture of the ligamentous union; wiring of the fragments twenty-three days after the re-fracture; continuous irrigation with boro-salicylic acid solution; imperfect approximation of the fragments; ligamentous union; joint stiff at end of three months; ultimate recovery of full power of extension and flexion without stretching of the ligament.

P. C——, aged twenty-seven, truckman, was admitted into Bellevue Hospital, December 13, 1883. On January 13, 1870, while at work, a cake of ice fell from a wagon and struck him upon the left patella. He fell to the ground and could not rise. The knee swelled and became ecchymosed. The doctor in attendance failed to recognize the true nature of the injury. The patient remained in bed about two months, the leg meanwhile becoming flexed. At the end of two months he began to walk about the house with the aid of chairs, and six months from the receipt of the injury, being unable to resume his former occupation, that of an ice-man, he became a truck-driver. He has always been obliged to favor the injured leg which has remained in about the same condition ever since.

On July 14, 1883, while some men were raising a heavy stone, the "dogs" slipped and the falling stone struck the patient upon the right knee-pan. He felt something crack, and fell to the ground. He tried to rise, but failed, and was carried home. The knee became ecchymosed and very much swollen. A splint was bandaged to the limb. By November 6th he could walk fairly well, and went to work.

December 8th he fell from his truck, bending his right knee under him. He felt something tear in the joint, was unable to walk, and the knee became very painful and swollen.

Upon admission the right knee was swollen and painful. There is a transverse fracture of the patella at its middle, with three-fourths of an inch separation of the fragments. On account of the old fracture of the left patella the patient is unable to extend that leg. Cold applications were made to the right knee-joint.

December 25th.—The pain and swelling are nearly gone.

Operation, December 31st.—The right knee-joint was opened by a transverse incision between the fragments. Irrigation with warm boro-salicylic solution was practised almost continuously during the whole operation. A thin ruptured ligament was found between the fragments. The underlying surfaces of the fragments were composed of a layer of very dense bone, which was cut away till a freely bleeding cancellous structure was reached. The fragments were drilled for two wires, but when these were passed it was found that the bones could be brought in contact only at their lower cartilaginous edges, and that they were separated by a wide gap at their upper surfaces. The synovial pouch was opened and drained with catgut at its most dependent part, at the outer aspect of the joint. Into each angle of the incision, which was well prolonged downward, was placed a medium-sized rubber drainage-tube. The different structures were sutured in separate layers with catgut, and the limb enveloped in an antiseptic dressing, and then suspended.

January 2d.—The patient complains of a dull pain in the operated knee.

January 13th.—The dressings are changed for the first time. The deep portion of the wound has united, but the superficial portion has opened through a too-early absorption of the catgut sutures. The limb was redressed, antiseptically, and placed upon a posterior splint.

February 1st.—The wound has all healed, except where it parted superficially. The patella fragments are apparently united. The posterior splint is still applied.

March 17th.—The wound is almost healed, and the patient is permitted to walk about.

March 21st.—There is a small ulcer on the outer side of the popliteal space surrounded by indurated tissue, and discharging a yellow serous liquid. Dressed with iodoform and gauze.

March 28th.—The patient eloped from the hospital with no motion in the joint. The wires had previously been removed.

In July, 1885, I had the opportunity of examining the patient.

In the left knee there was a transverse fracture of the patella near the middle, without even a ligamentous union of the fragments, which were separated three and one-half inches when the limb was quiet in the extended position. The upper fragment could be brought downward one inch. The ligamentum patellæ was so much shortened that the lower fragment was close against the tubercle of the tibia. Some of the lateral aponeurotic fibres of insertion of the quadriceps were very much hypertrophied, but there was no power of extension. This knee sometimes swells and pains him.

The right knee shows no line of depression between the patella fragments, which, when carefully tested, have a slight independent motion, laterally. They are united by a firm, short ligament that has not lengthened as function of the joint has been regained.

When the patient left the hospital the knee joint was solidly stiff, and he walked without crutch or cane. In about six weeks he could bend the leg to a right angle with the thigh, and in two months had perfect function. The knee, tested by working at the same occupation as before injury, was in every respect just as strong as it was when in normal condition.

Each of the above detailed operations lasted more than three hours. This was mainly due to a faulty plan of procedure, and led me to remodel the operation with a view of reconstructing the joint in the most complete manner, in the shortest time. I shall describe the different steps of procedure with a minuteness justified by their importance in contributing to a successful result.

The operation, it is always to be borne in mind, is undertaken only for the sake of restoring the function of

the joint, and since other methods of treatment often yield good results without danger to life or limb, the onus laid upon this operative procedure is that it shall produce better function in the limb with safety to the patient. In all steps of the operation, therefore, the factor of safety of the life of the patient should be of controlling importance.

The antiseptic measures are as follows: The operator and his assistants thoroughly cleanse their hands and forearms with soap and water and then disinfect them by repeated immersion in a 1 to 30 watery solution of carbolic acid. The same kind of antiseptic solution used for the skin disinfects the instruments, which should lie in the bath for at least twenty minutes before commencing the operation. The patient's uninjured extremity is wrapped in a blanket, and further protected with a waterproof covering of rubber cloth or other material. The whole of the injured limb is thoroughly scrubbed with soap and water. The region of the operation receives especial attention, and the whole circumference of the limb for quite a space about the knee-joint is thoroughly lathered and shaven clean. The soap is then washed off with a warm 1 to 30 solution of carbolic acid or a 1 to 2,000 bichloride of mercury solution. The leg and thigh are separately enveloped in towels soaked in a 1 to 2,000 bichloride solution. The towel covering the leg and foot should be held in place by a few turns of antiseptic bandage. The thigh towel may be secured by pins, and should be loosely applied so as not to constringe the limb. Around the limb at the knee-joint, which has been left bare for an extent of about eight inches, is wrapped a towel soaked in a 1 to 30 solution of carbolic acid; it infringes upon the leg and thigh coverings and is pinned together over the anterior aspect of the limb. The operating-table should be so arranged that continuous irrigation can be carried on without wetting the bedclothes. Care should be taken that the limb is not sunk in a trough, but that the whole construction for irrigation shall allow free access to the operative field.

The limb, thus enveloped, is further isolated from contaminating contact with a wide area by means of towels wrung out of a 1 to 2,000 solution of the bichloride of mercury, placed beneath it and covering encroaching bedclothes. After all these preparations have been completed, and not till then, the patient is etherized. Meanwhile the limb is preserved extended in position and the towel about the knee-joint is kept wet with the warm carbolic-acid solution.

The irrigant employed is a warm solution of the bichloride of mercury. The strength of the solution is determined by its irritant effect upon the cavity of the joint and the intensity of the septic impression to be combated. Keeping in mind always the safety of the patient, the strongest solution should be used that will not produce injurious irritation. In a pure atmosphere sterilized water will doubtless preserve the asepticity of the wound, yet there can be no objection, even in the most favorable surroundings, to employing the strongest defence that is efficient against a highly charged septic atmosphere, provided the solution is not unduly irritant. The strength I have fixed upon after some experience is 1 part of bichloride to 4,000 parts of water. With this strength of solution adhesions form in the joint. Since they do not prevent the recovery of function it would be an unjustifiable line of experiment, for the purpose of avoiding adhesions, to determine how weak a solution can be used under exposure to the strongest risk of sepsis. The chance of poisoning from absorption of the mercury may be dismissed from consideration. I have seen no such effect in any wound from the use of solutions of 1 to 1,000 and weaker, having always, however, been careful that accumulations of the solution have not been left in cavities of the wound. The solution should be a little more than blood warm, to avoid lowering the vitality of the joint. The irrigant should flow continuously or with short interruptions over the wound from the beginning to the end of the operation. The weaker the solution the more the reason that the exposure breaks in this antiseptic medium should be as few as possible.

The patient having been fully anæsthetized the operative field is exposed by simply unpinning and laying back the towel enveloping the knee. During the whole operation the limb should not be flexed but always remain in the extended position. An assistant now directs the irrigating stream in an even sheet over the field of operation.

The operator stands next the injured limb, his principal assistant opposite. In this, as in most operations conducted under irrigation, to diminish the risk of miscarriage of asepsis, I restrict my assistant to the use of one sponge; it must not leave his hand, and indeed, had best be tied to his wrist; it may be cleansed, as required, under the stream of the irrigant. The assistant to hand instruments, while a convenience, is not absolutely necessary, and may be dispensed with. Throughout the operation the operator and assistants, after having once been disinfected, should not contaminate themselves by touching anything not disinfected, but persistently remain aseptic.

A transverse incision about three inches long is made through the skin over the anterior aspect of the joint in the interval between the fragments. Too much force should not be given to the stroke lest the lacerated subcutaneous tissues be unnecessarily sliced. Generally when the skin is incised the joint is opened and there is an escape of bloody liquid and clots, but exceptionally the immediate subcutaneous tissues are intact while the deepest layer is lacerated. The joint having been opened, the left forefinger is introduced, and by a delicate touch the extent of the rent in the capsular structure is appreciated. The skin incision is then extended to fully expose its limits. In recent fractures it seems to me that the transverse incision should be preferred to a longitudinal one, as it exposes the torn capsular structures for operative repair. In old fractures it would seem, however, more advantageous to adopt the longitudinal incision for the better access to the upper fragment and the tendon of the quadriceps. Since, however, in three instances of refracture that were compound that have come under my notice, the transverse scar was in each instance the starting-point of the laceration opening the joint, I am disposed to regard with some favor the longitudinal incision. While the torn capsular structures may not be so easily reached and effectively repaired through such an incision, yet these disadvantages might be outweighed by the diminished risk of the refracture becoming compound. Perhaps it may be better to locate the scar away from the plane of fracture by opening the joint by a curved incision with the convexity above, thus forming a flap. An oblique incision has the disadvantages of the transverse and longitudinal ones without a compensating gain. The clots in the interval between the fragments are gently cleared away with the fingers and the irrigating current. Let it be borne in mind that the cavity of the joint before incision is, from a surgical stand-point, absolutely pure, and that the purpose of the irrigation is not to cleanse the joint of impurities, but to afford an antiseptic protective envelope for the tissues during the surgeon's manipulations; and, since the antiseptic solution is also an irritant the surgical procedures should expose the delicate synovial membrane as little as possible to its action. In gently removing the clots there may be found, if the fracture is several days old, the delicate membrane described by Van der Muelin extending between their lower fractured surfaces from cartilage to cartilage. This structure, which is probably the organized under-surface of blood-clot, is so delicate that it breaks under very gentle disturbance, and then is but an incomplete partition between the fragments shutting off the cavity of the joint. It may be disregarded and wiped away. The torn capsular structure covering the patella, and most likely found infolded over the fractured surface of one or both fragments for a greater or less ex-

tent, are greatly peeled from the underlying bone by means of a sharp spoon. These tissues should not be pushed away from their normal attachment at the upper surface of the bone, baring it of periosteum; neither should this tissue be cut away unless it be so shredded as to be clearly lifeless. It should be preserved to cover and strengthen the line of fracture. The fractured surfaces are lightly scraped free of clots or granulations by the sharp spoon, and the bones are then ready for drilling. The skin-flap is sufficiently retracted and the crotchet drill (see Fig. 1) is pushed through the immediate covering of soft parts to the bone, in which it is engaged by giving it partial rotatory motions, always under light pressure. The drill should never be withdrawn till the hole is drilled, but constantly urged onward by rotatory motion and even pressure. The finger watches for its egress, and as the point nears the surface it is made to cut its way slowly with lighter pressure. Thus handled there is no danger of fouling or breaking of the drill. My own drills are more delicate than those generally sold, and I have not yet broken one. It drills a hole just large enough to take the wire. Too large a hole exposes the bone to the risk of a partial caries. As a general procedure the fragments should be drilled from without inward, the point of the drill passing toward the cavity of the joint. Exceptionally one of the fragments has such lax attachments that it can be tilted, so that the drill can be inserted at the bony cartilaginous junction. The fragment at the surgeon's right hand should be drilled with the right hand, the left hand fragment with the left hand. A loop of silk is thrown over the hook in the drill and is drawn through the bone. When the silk cannot be adjusted to the hook of the drill with the fingers it can be lodged in position by the fork shown in Figs. 2 and 3. In case these loops lie away from the joint they are easily reversed by using them as guides to draw new loops into position. To prevent their displacement the ends of the thread are drawn through the loop. In case there is much difficulty in retracting the skin the drill may be driven directly through the skin and intervening soft parts covering the bone, and afterward entered alongside of the wire where it comes through the skin, and carried along the destined path of the wire superficial to patella. A loop of silk drawn after the drill enables the operator to pull the tapered end of the wire back through the skin into position. See Case No. VII.

FIG. 1.—*a*, Crotchet Drill, two-thirds actual size; *b*, end of Drill, actual size.

For the nice approximation of the fragments only one wire should be used. A large piece of bone broken from a main fragment may be wired to it, but small pieces that fit into place do not require suturing.

In drilling, a large bite of bone should be taken, by entering the drill a considerable distance, say about three-fourths of an inch, from the edge of the fractured surface. If the bone is drilled near to its fractured edge the wire is apt to cut through the thin layer of cancellous structure. It is an error not to carry the wire deeply. A superficially placed wire hinges the fragments by their upper edges, and the fragments may be separate at their lower edges while they are in contact above. This may account for the failure to secure bony union in some cases after wiring. While it is desirable to drill in a line projected through the bony cartilaginous junction on the fractured surface, it is better in erring to carry the point of the drill further back, having it emerge through the under surface of the cartilage rather than higher up on the fractured bony surface. In the former case the wire can be sunk to the bone, as was done by Lister, by gouging away the overlying cartilage. The wire may pass over the cartilaginous surface of one fragment to that of the other with no evil effects. In the case of a soft suture, as silk-worm gut, I am inclined to think this the preferable plan of placing the suture. When the drill emerges in a faulty position upon the bony surface, the change of its direction must be corrected by its re-insertion. It is important that the deep portion of the suture shall pass from one fragment into the other at corresponding points, else the sutured pieces will be upon different planes, and through the lessened amount of bony contact the patella will not be ultimately restored to its maximum strength. Again, the wire passing out of the cancellous bony structure is more apt to tear in the bone when tightened, than when it dips through to the cartilage. Wire No. 3 or 4 of the French catheter scale is of the most advantageous size. Larger wire cannot be easily manipulated.

By the method of procedure that has been detailed the surgeon is enabled to suture the fragments with any kind of suture, under all conditions of breakage, with a minimum disturbance of the structures of the joint. At the same time, the simple hand-drill enlarges the scope of the touch, an advantage not afforded by more complicated drilling machinery.

The fragments having been drilled and the conducting loops of silk lodged in position, provision is made for drainage by introducing the author's large aluminum probe, properly curved and armed with a drainage-tube, beneath the fragment into the most dependent portion of the synovial sac at its outer aspect. The end made prominent beneath the skin is cut down upon, and the opening, if necessary, enlarged by the blunt bistoury. The thread carrying the drainage-tube is thrust through into view, and the drain-tube pulled into position. The curved dressing forceps passed into the joint may be used instead of the probe to make the opening. Care should be taken that the tube does not extend too far into the synovial pouch, and that it is not closed by being pinched against the external condyle of the femur. The free delivery of the tube should be attested by slightly lifting the upper fragment as the irrigating stream is directed into the joint. After being cut short to the surface of the limb, it is held from inward displacement by a safety-pin. The wire or other material used for the suture is pulled into position through the bones, by means of the guiding loops of thread. If wire is used, its ends are tapered and bent sharply, to catch into the loops of thread and offer no resistance in passing through the bone. The ends are drawn from within the joint outward, through the fragments. The soft parts over the patella are incised, so as to allow the suture to sink to the bone when it is fastened. The wire is twisted by hand five or six turns, cut short, and its stump turned down. The torn synovial membrane and capsular structures, as well as the edges of the incisions made to sink the wire, are brought together, without trimming, by a medium-sized continuous catgut suture. Sometimes two layers of capsular structures can be distinguished and separately sutured. Careful suturing of these layers not only adds to the strength of union of the fragments, but, to some extent, protects the joint from infection proceeding from the skin incision inwardly. The skin wound is best united by interrupted sutures of coarse antiseptic silk, rather widely inserted. If the skin gapes between the sutures, its edges may be held in perfect apposition by a continuous suture of the smallest catgut. It is advisable to leave the dependent angles of the skin wound quite open for drainage. If there has been much dissection of the connective tissue between the capsule and the skin, either by the knife or injury, pieces of small-sized drainage-tubes should be inserted at the appropriate places in the wound, or through counter-openings, to prevent wound secretions from accumulating in the pockets. The irrigation is not stopped till the sewing of the wound has been completed.

The limb is dressed in the following manner: A narrow strip of protective is placed over the line of incision, to prevent adhesion of the dressings to the wound. The region of the wound, especially about the drainage-tubes, is dusted with iodoform. Bichloride gauze, wet in a solution of 1 to 30 carbolic acid, is wrung nearly dry, and loosely applied about the joint. Over this layers of bichloride gauze are applied, covering in several inches on the thigh and leg. When a sufficient amount of gauze has been applied to absorb at least the discharges for four days, the limb, from the ankle to the groin, is enveloped in a layer of "combined dressing," consisting of a sheet of borated or bichloride cotton held between layers of antiseptic gauze. This is bandaged in position with antiseptic bandages. Five or six perforated tin strips, invented by the author for immobilizing bones in the treatment of simple and compound fractures, are placed upon the anterior surface of the limb, and secured by an antiseptic bandage. Finally, the limb is placed in a well-padded fracture-basket of wire gauze, and, if more agreeable to the patient, it is suspended.

The wound should be redressed about the fourth day, and the drainage-tubes removed. This dressing should be conducted with all the care of the primary operation so far as relates to antisepsis. The wound should be exposed under irrigation with bichloride solution not weaker than 1 to 2,000. Especial care should be used to irrigate about the drainage-tubes, as the tubes are removed, but the streams should not be forced into the joint. It is probable that the drainage-tubes fulfilled within the first twenty-four hours the purpose of drainage, but the objection to their earlier removal is the chance of disturbance of a barely united wound.

The next dressing of the wound can be postponed for a week or ten days, when the silk sutures may be removed.

Motion in the joint should be commenced, the wound having soundly healed, by the third week.

The purpose of wiring the bones with strong wire, in preference to using a weaker suture, as already stated, is to afford opportunity for early motion in the joint without separation of the fragments. If motion is to be delayed till the bone is solid, the wire suture should be discarded, and with it the remote risks attendant upon refracture. When the fragments are wired the patient is most likely committed to a second operation in case of refracture, and this may take place under circumstances that are very disadvantageous. Inasmuch as patients practically refuse to have the wire removed after its temporary usefulness has passed away, it becomes a question, in view of the risks entailed by a refracture, whether the wire should ever be used. Certainly the principal justification is its firmly holding the fragments in the early period of motion in the joint.

The sooner motion is begun in the joint after the wound in the soft parts has healed, the quicker will its function be restored; at first the motion should be passive and gentle, with the idea of not provoking any irritation. After a few days the patient should practise active motion, flexing the leg without lifting the heel from the bed. The reviving of the function of the synovial membrane, the suppling of the soft parts by massage and douches, the stimulation of the muscles by the will, prepare the way for an increasing range of motion. The gain in the amount of motion should not be forced out of proportion to the rate of progress toward health in the soft parts; otherwise irritation and reaction will be provoked and the progress retarded. The patient should be encouraged to persevere in increasing the range of motion till full power of flexion is achieved.

A suitable protective apparel limiting the range of flexion will guard against refracture.

The following instances of operation were under this improved method of operation.

Case III.—Simple fracture of the patella from direct violence; wired on the ninth day under constant irrigation with 1 to 2,000 bichloride solution; infolded fibrous tissue upon the fractured surfaces; drainage-tubes removed on seventh day after operation; primary union; passive motion begun after four weeks; bony union of the patella; at end of one year motion to a right angle.

J. R——, aged twenty-one, was admitted into Bellevue Hospital, October 12, 1884. The patient, a healthy man, while partly under the influence of beer the day before his admission, was clubbed by a policeman upon the left knee, knocking him down. He could not rise unaided, but with the assistance of friends walked to Chambers Street Hospital, where a splint was applied. He was then sent to Bellevue Hospital.

Examination shows the left knee to be swollen. There is a transverse fracture of the patella through its middle, with three-fourths of an inch separation of the fragments. A posterior splint was applied to the limb and an ice-cap to the knee.

October 21st.—The patient was operated upon before the class of the Post-Graduate Medical School. Irrigation with a warm solution of bichloride of mercury, 1 to 2,000, was continued throughout the operation. A considerable quantity of clotted blood was removed from between the fragments, which were exposed by a transverse incision. The torn aponeurotic structures on the anterior aspect of the patella were turned in upon and adherent to the fractured bony surfaces of both fragments, thus completely preventing bony contact when the portions of bone were brought together. This tissue was lifted, but not cut away. Both fragments were drilled from without inward toward the cavity of the joint. In addition to the tube inserted through a counter-opening on the outside of the joint at the most dependent portion of the synovial pouch, a short piece of small tube was introduced through a gap at the inner side of the patella. The capsule and aponeurotic expansion of the quadriceps were separately sewed with catgut continuous suture; the skin incision was closed by interrupted sutures, between which was run a fine continuous catgut suture. The operation lasted one hour.

October 25th.—The patient had some pain in the knee for two days after the operation.

October 28th.—The dressings were removed under irrigation. They were soiled by only a small amount of discharge. There is primary union of the skin-wound and less swelling of the knee than before the operation. The drainage-tubes were removed and the limb was redressed as after the operation.

November 10th.—There are only two small granulating surfaces that mark the places of exit of the drainage-tubes. The limb is redressed as before.

November 18th.—The wounds are entirely healed and the bony union of the patellar fragments is apparently firm. A posterior splint was applied.

The highest temperature after the operation was 100.8° F. It was normal after the fourth day.

November 21st.—Passive motion was commenced, and the leg flexed through ten degrees without any exertion and with very little pain.

November 22d.—Passive motion is practised daily.

November 24th.—All apparatus is removed and the patient voluntarily exercises the joint.

December 9th.—The patient was allowed to go home. He walks without assistance from crutch or cane.

December 27th.—The patient walks well without limping. He can bend his knee to an angle of forty-five degrees. The patella is freely movable. He was this day discharged from the hospital.

October 10, 1885.—The patient has motion to a right angle. The skin is loose and slides over the subjacent tissues in the region of the scars. The patella is somewhat enlarged, especially laterally, and it is not quite so movable laterally as the opposite one.

March 16, 1886.—There is good lateral motion of the wired patella, which is somewhat enlarged longitudinally and transversely. The patient has perfect command

over extension, but can flex the leg only to a right angle with the thigh. He states that he has never taken any pains to bend the knee further than required in walking. He never has pain in the knee and the location of the wire can hardly be discovered.

Case IV.—Simple fracture of the patella, probably from muscular action; wired under irrigation with 1 to 4,000 bichloride solution; interposed fibrous tissue; tubes removed on fourth day; passive motion on sixteenth day; primary union of wound; bony union of the patella with nearly perfect function in the joint at the end of six months.

F. L——, aged forty-two, plumber, was admitted into Bellevue Hospital, August 4, 1885. The patient has always been healthy. In descending a flight of steps he fell backward upon his nates, as he fell he suddenly drew up his legs and felt a sharp pain in the left knee.

Examination shows considerable swelling and ecchymosis about the joint. There is also ecchymosis over a broad area posteriorly, extending down the leg from the bend of the knee nearly to the ankle. A transverse fracture of the patella is detected. The limb was placed upon a posterior splint and the knee bandaged with a gauze bandage wet with lead and opium wash.

August 5th.—The patella is found broken transversely at its middle; the fragments are separated three-fourths of an inch and there seems to be considerable effusion between them. The limb is kept upon the posterior splint and the joint is bandaged with gauze, which is kept constantly moist with the lead and opium wash. He complains of pain in the metatarso-phalangeal joint of the left great toe; the joint is red and swollen.

August 10th.—All redness and pain have subsided from the toe-joint.

Operation, August 10th.—The wiring of the fragments was conducted in the usual manner, under continuous irrigation with a warm solution of bichloride, 1 to 4,000. When the joint was opened the shreds of torn fibrous tissues, in which some blood-clot was mingled, were found wrapped over the fractured surface of the upper fragment, completely concealing it. This torn tissue was about two inches in length and shredded as if it had been combed; a portion of it, being lifeless, was cut away. The membrane described by Van der Meulin was seen. The fractured surfaces were lightly scraped with a sharp spoon, and then brought together with a single wire. In addition to the usual drainage-tubes into the joint on its outer aspect, another tube was passed through a gap in the tissues on the inner side of the patella. The limb was dressed in the usual manner.

August 14th.—The dressings were removed. They were stained with a sero-sanguinolent discharge. There are no signs of inflammation. Both drainage-tubes were taken away. They contained only a little bloody serum. The limb was re-dressed in the same manner as at first.

August 24th.—The union along edges of the wound is complete except where the drainage-tubes emerged. A slight amount of motion was made in the knee-joint. The limb was re-dressed.

August 26th.—The splint and dressings were removed and the patient flexed the leg to an angle of ten degrees. It was directed that the joint should be moved every alternate day.

September 2d.—The lateral mobility of the patella is nearly as great as normal.

October 27th.—The patient was discharged from the hospital. He could walk without the aid of a cane, and could flex the leg at an angle of forty-five degrees.

February 1, 1886.—There is no notching at the side of the wired patella, which, while not increased in length, is one-fourth of an inch broader than the opposite one. It cannot be moved quite so freely laterally as the uninjured one. He can bend the injured limb past a right angle, but not quite to full flexion. He can go up and down stairs as well as ever. So far as relates to the knee he could work as well as ever at his former occupation, that of a stevedore. The wire cannot be felt, nor has it occasioned any inconvenience.

Case V.—Simple fracture of the patella, probably from direct violence; wired sixteen hours afterward, under irrigation with 1 to 4,000 bichloride solution; fibrous tissue infolded; drainage-tubes removed on the second day; primary union of the wound; bony union of the patella; ultimate perfect recovery of function in the joint.

T. N——, aged forty, was admitted into St. Vincent's Hospital, August 22, 1885. The patient has always been healthy, but a very intemperate drinker. At about eight o'clock on the evening of admission, while intoxicated, he was thrown down and sustained an injury to the right knee. On examination there is found a transverse simple fracture of the right patella through its middle, with about three-fourths of an inch separation of the fragments. There is no swelling of the joint nor evidence of contusion, and the fragments of the patella can easily be brought together and crepitus obtained. A posterior splint was firmly bandaged to the limb and an ice-cap applied to the knee. The patient's restlessness was quieted by morphia and bromide of potassium.

Operation, August 23d.—The immediate effects of the alcohol have passed off, but the patient's hands and tongue are quite tremulous. At 12 M., sixteen hours after the receipt of the injury, the joint was opened under constant irrigation with the 1 to 4,000 solution of the bichloride of mercury. The deeper structures were torn transversely from side to side of the joint. There were no clots in the joint. The fibrous structure over the patella overhung the broken bony surface of the upper fragment. This was lifted and the few small clots of blood on the fractured surfaces dislodged by touches of the sharp spoon and the irrigating stream. The line of fracture was irregular from side to side, the upper fragment being indented at its middle. The lower fragment was also fractured near its outer side, the line of fracture, however, extending vertically only part way through the bone and then horizontally. The small piece of bone thus broken off was firmly adherent. The two principal fragments were brought together with a single wire, each one, on account of its mobility, being drilled from the bony cartilaginous junction on the fractured surface from within the joint in a direction outward. In addition to the usual provision for the drainage of the joint at its outer aspect, another tube was inserted through a counter-opening to drain a subcutaneous pocket over the anterior surface of the knee. The ends of the drainage-tubes were left long, and were surrounded by the deeper dressings. Pieces of catgut tied to the ends of the tubes passed obliquely through the dressings.

October 25th.—The tube on the inner side of the joint was withdrawn by means of the attached string. In attempting the removal of the other tube its end caught in the dressings and the traction string gave way. It was thought probable that the tube had been withdrawn from the joint though lodged in the dressings.

September 2d.—The dressings were removed; the deep portions were stained by a sero-sanguinolent discharge. One quarter of an inch of the remaining drainage-tube was still lodged in the wound. The transverse incision had healed by first intention, the continuous catgut suture used to bring the edges of the wound together was not yet absorbed. There was a granulating surface at the place of exit of the outer drainage-tube. A light antiseptic dressing was applied about the joint and the limb bandaged in the wire box that served as a posterior splint. The temperature after the fourth day was normal.

October 9th.—The patient had motion to thirty degrees.

January 29, 1886.—The patient went to work at a foot-lathe the latter part of December. The knee swelled and he was obliged to stop working. The wired patella is considerably hypertrophied, being three-eighths of an inch wider and somewhat longer than the uninjured one. The wire cannot be felt and gives no trouble. The sides of the patella are not notched. Its lateral motion is some-

what limited. He has pain in the knee when the weather changes. He can flex the leg past a right angle and is gaining in range of motion every day.

January 16, 1887.—The wired patella is markedly hypertrophied. The thigh is slightly atrophied. There is normal power of extension and flexion. The knee never inconveniences him.

Case VI.—Simple fracture of the patella, probably from muscular action; wired on the fifteenth day under irrigation with 1 to 4,000 solution of bichloride of mercury; infolded tissue upon both fragments; drainage-tube removed on the second day; passive motion begun at the end of two weeks; bony union of the fragments; ultimate recovery of complete function in the joint.

H. L——, aged twenty-six, was admitted into Mount Sinai Hospital, August 4, 1885. The patient, though obese, has always been healthy. The night before admission he slipped on the floor, and just as his left knee struck he felt something snap in the joint. He was unable to get upon his feet and the joint began to swell immediately. On admission, the left knee-joint was found much swollen and tender. There was simple transverse fracture of the patella at its middle, with three-fourths of an inch separation of the fragments, which could be forced together and crepitus obtained. A broad piece of adhesive plaster was applied to the anterior surface of the thigh and another piece to the same region of the leg. The patella fragments were then brought together by a lace carried through the ends of plaster. The limb was elevated upon a pillow and an ice-cap applied to the knee.

August 6th.—There is much ecchymosis on the inner side of the joint. A posterior splint was applied to the limb.

August 10th.—The patient feels pretty comfortable.

August 15th.—Preparatory to wiring the ice-bags and dressings were removed and the limb elevated to get rid of the œdema. There is an abrasion of the skin on the inner side of the joint.

Operation, August 18th.—Fifteen days after the receipt of the injury the joint was opened under constant irrigation with a 1 to 4,000 warm solution of the bichloride of mercury. There was a slight amount of clot in the joint. The torn fibrous structures upon the anterior aspect of the patella were infolded and adherent to the fractured bony surfaces of both fragments. The membrane described by Van der Menlin was observed. The infolded tissue was peeled from the bone and the fragments brought together in the usual manner with a single wire. The operation was completed in forty-eight minutes, fourteen minutes being spent in sewing the wound.

August 19th.—The patient has had some pain in the knee but not enough to prevent his sleeping.

August 20th.—The dressings were taken off under irrigation. There has been hardly any discharge. The edges of the transverse incision have united by first intention. The drainage-tube was removed.

August 31st.—The transverse incision is firmly united. The wound at the place of exit of the drainage-tube is cicatrizing. The posterior splint was applied.

September 4th.—The small ulcer at drainage site has nearly healed. The posterior splint is left off and passive motion of the joint is begun.

The highest temperature by rectum after the operation was 101° F. After the fourth day it was normal.

December 21st.—The patient can flex the leg past a right angle. He has nearly the same range of motion as upon the healthy opposite side.

March 18, 1886.—Since January the patient has been at the same work as before he was injured. The function of the injured limb is as perfect as that of its opposite healthy fellow. The patella is of about the same size and has the same lateral mobility as the unbroken one. The wire cannot be felt, nor has it caused any discomfort.

Remarks.—This case, in comparison with the preceding one, suggests that the nearness of time of operation to the date of injury has no perceptible influence over the ultimate recovery of motion in the joint. The early and persistent efforts at motion on the part of the patient are the major factor.

Nearly one-third of the whole time of the operation was consumed in sewing the soft parts. The length of the operative procedure is in proportion to the thoroughness with which the integrity of the joint is restored.

Just before the operation, two weeks after the receipt of injury, the fragments were freely movable independently, and at the operation the only trace of ligamentous union was the delicate membrane extending between their deep edges.

Case VII.—Simple fracture of the patella, with much effusion in the joint; joint tapped; fragments wired on the fourteenth day, under irrigation with a 1 to 4,000 bichloride solution; no infolded fibrous tissue; bony union without suppuration; recovery at the end of six months, under adverse circumstances, of perfect power of extension and flexion to forty-five degrees.

M. B——, aged sixty-four, pedler, was admitted to Mount Sinai Hospital, July 2, 1886. The patient has always been a healthy man. Two months ago he fell, striking on the left knee, which became swollen and discolored, and confined him to bed for two weeks. It was treated with cold applications and a compressing bandage. He was examined at a dispensary, and was told that no bones were broken. After this accident his knee was quite stiff. Three days ago, while walking on the street, the patient fell and struck his injured knee, which soon became very much swollen and discolored.

On admission the left knee is tensely swollen and ecchymosed. In some places the skin is vesicated. The swelling and ecchymosis correspond to the situation of the synovial sac. The left knee is two inches greater in circumference than the right. The leg was placed upon a posterior splint, and lead and opium wash was applied to the joint.

July 4th.—The knee-joint is still very much enlarged. Under elastic compression the joint was antiseptically tapped with a trochar and cannula, and eleven drachms of dark, liquid blood were withdrawn. As the joint was not much reduced in size, it was concluded that it contained a large amount of clot.

Operation, July 13, 1886, under continuous irrigation with a 1 to 4,000 bichloride of mercury solution. Upon making the usual transverse incision into the joint, a considerable quantity of liquid blood and a few granules of bone escaped. A large amount of clot was found between the fragments. There was no infolded fibrous structure upon the fractured surface of either fragment. The surfaces of bone were lightly scraped free of gran-

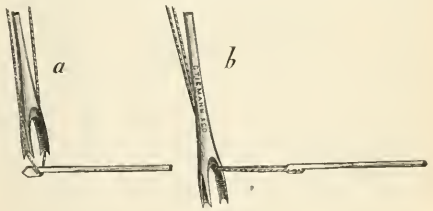

Fig. 2.

ulations. The transverse fracture had taken a very oblique direction through the thickness of the bone, so that the broken bony surface of the upper fragment widely overhung its cartilaginous margin. In drilling the upper fragment, deceived by the obliquity of the fracture, the point of the drill was made to emerge through cancellous tissue some distance above the bony cartilaginous junction. However, the guide of silk was temporarily drawn into position. As the lower fragment could not be readily exposed, the drill was passed directly through the skin and soft parts to the bone, its point emerging through the under surface of the cartilage. It was clear that when

the fragments would be wired together the upper fragment would be on a lower plane than the lower one, and that the apposition would be quite imperfect. The misdirection of the hole through the upper fragment was corrected by drilling again, directing the drill even a little upward to insure the exit of the point through the under surface of the cartilage. By means of a properly constructed instrument (see Fig. 2) the silk loop was cast over the notch in the end of the drill, which could be only reached by the tip of the finger. One end of the wire was drawn through the upper fragment, and the other through the lower fragment and the skin. The drill was again introduced alongside of the wire emerging through the skin, and passed superficially to the upper surface of the fragment. By means of a loop of silk drawn along the track of the drill, the wire was made to re-enter its opening of emergence through the skin and was pulled into place. (See Fig. 3.) A drainage-tube was passed

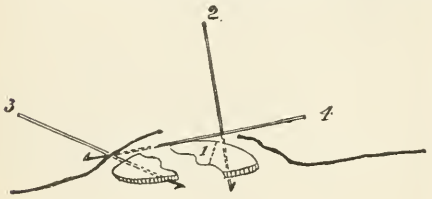

FIG. 3

through the most dependent portion of the synovial pouch on its outer aspect. After lightly scraping their fractured surfaces the fragments were brought into exact apposition. The wire was cut short to the twist, and its stump was turned down. The capsular fibrous structures were sewn with medium-sized continuous catgut suture. The superficial wound was drained by three short pieces of small-sized drainage-tube. The skin incision was united by interrupted sutures of coarse silk, between which was run a continuous delicate catgut suture. During the whole operation no vessel required ligation. The wound was dressed with antiseptic gauze, and confined upon a posterior splint in the usual way.

July 17th.—The patient has been perfectly comfortable since the operation. The wound is dressed for the first time, under irrigation with a 1 to 1,000 bichloride of mercury solution. There is not much discharge upon the dressings. There are no signs of inflammation. The drainage-tubes were removed. The knee was re-dressed with gauze, etc., in the same manner as after the operation.

July 23d.—The wound was dressed, no irrigation was required. It was entirely healed, except at the places of exit of the drainage-tubes, which are marked by spots of granulations. The silk sutures are removed. A light antiseptic dressing and the posterior splint were re-applied.

July 28th.—The wound is entirely healed. The splint is left off during the day, and passive motion of the joint is cautiously begun. The highest temperature was 101.2° F. on the night of the operation; on the second day thereafter it fell to normal, where it remained.

August 8th.—The patient is allowed out of bed, wearing only a short posterior splint.

August 15th.—There is swelling of the limb, and infiltration of the soft parts about the joint. The patient is about the ward on crutches. The limb is douched daily with hot and cold water, alternately applied.

August 30th.—The infiltration over the knee is passing away. The patient walks quite well, using only a cane.

January 17, 1887.—The patient for some time has been at work peddling. Since he left the hospital he has not treated the joint intelligently. He has wrapped a cloth around the knee, tied it with a string above and below the joint. The string above the joint deeply creased the skin and caused some œdema. The excursion of the patella, laterally, is limited. There is firm bony union. He can extend the limb perfectly horizontally, and flex it to an angle of forty-five degrees. He walks without a cane. He was directed to remove all constricting dressings, to douche the limb daily with cold water, and by proper movements to increase the power of flexion.

Remark.—This case illustrates the capability of this method of wiring to overcome unusual difficulties. Without loosening the patella by further dissection, it would have been impossible by other procedure to have sutured the fragments with the nicety and firmness with which it was easily accomplished. It is evident that by this same method a suture of other material could have been applied with facility.

CASE VIII.—Simple fracture of the patella, probably from direct violence; operation under irrigation with 1 to 4,000 bichloride solution; lower fragment loose in the joint and removed; no infolded tissue upon the upper fragment; suture of the ligamentum patella to the upper fragment with silk-worm gut. Union without suppuration; at the end of four months perfect extension with flexion to nearly a right angle and improving. Ultimate recovery of nearly perfect flexion.

W. S——, forty-three years of age, cigar-maker, was admitted into Bellevue Hospital, September 6, 1886. This patient was kindly referred to me for treatment by my colleague, Dr. J. W. S. Gouley. He has always been in good health. One hour and a half before admission into the hospital, while in a saloon, he was pushed from behind, and falling struck his flexed left knee upon the floor. He could not rise or use his leg, and thought it was broken. He crawled to the sidewalk, hailed a policeman, and was put into an ambulance. He could not bear his weight upon the left leg or use it at all.

The whole left knee is much swollen and ecchymosed. There is a transverse groove at the junction of the upper two-thirds and the lower third of the patella, with one-half an inch separation between the fragments. They can be brought together and what appears to be bony crepitus is obtained. An ice-cap is applied to the knee.

September 10th.—Poultices are applied to the knee.

September 16th.—The swelling of the knee has subsided considerably. The lower fragment is thought to be fractured into two pieces.

Operation was performed September 18th, under continuous irrigation with a 1 to 4,000 bichloride of mercury solution. A considerable amount of clot and liquid blood was found in the joint. The cartilaginous face of the lower fragment presented toward the surface. The fragment was entirely loose in the joint and was picked out. This piece of bone was the whole of the lower fragment, with the exception of a small piece about the size of a pea in the outer side of the joint remaining attached to the ligamentum patellæ, and a very thin crust from the anterior surface which adhered to and roughened the ligament. The fragment had been torn off apparently by a movement of rotation. Even the small attached bit of bone showed the force of the twist. Its presenting cartilaginous surface was cut off with scissors. There was no infolding of fibrous tissue upon the upper fragment. The bone granulations covering its fractured surface were lightly scraped off. The upper fragment was bored from without inward toward the cavity of the joint. The bone was noticeably hard. The ligamentum patellæ was drilled from without inward toward the joint cavity. A drainage-tube was passed through the place of election. Two strands of disinfected silk-worm gut were drawn into position by means of loops of silk, and the incrusted end of the ligamentum patella, feeling as if sanded, was fitted against the fractured bony surface of the upper fragment and secured. The torn synovial sac and fibrous capsule were then separately sutured with a continuous catgut suture. The cut edges of the skin were brought together with interrupted sutures of disinfected silk.

The usual antiseptic dressings of bichloride gauze and combined dressings were applied. The limb was immo-

bilized by tin strips and then placed in a wire-gauze fracture box.

September 22d.—Knee dressed. There is primary union throughout the whole extent of the wound. There is no swelling. The drainage tube is removed.

September 28th.—The knee was dressed. The silk sutures were removed.

The temperature fell to normal on the sixth day after the operation.

October 10th.—No swelling in the knee. There are still a few granulations at the drainage-tube counter-opening. There has been quite a growth of bone, especially on the outer side of the patella, which now has an oblong shape.

The splint was removed and active and passive motion begun, the patient remaining in bed.

November 21st.—The patient left the hospital with motion of fifteen degrees.

January 15, 1887.—The growth of the sutured patella on its outer side is marked, but does not interfere with motion in the joint. The knot of the suture can be felt beneath the skin. There is power of perfect extension horizontally, and flexion to nearly a right angle. The range of motion is daily improving. The thigh on the injured side is somewhat smaller than its opposite.

February 10, 1890.—It is now more than three years since the operation. The left patella is hypertrophied, being somewhat longer and wider than the right one. Its shape is oblong, being especially lengthened on its outer side. The scar of the operation is perfectly movable. The silk-worm gut sutures can still be felt. There is perfect power of extension, and power of flexion past a right angle. The full extension seems to be limited by the increased length of the patella. The patient goes up and down stairs as well as ever; he can even kneel upon the floor and the joint never shows weakness.

Remarks.—Although this patient was examined after the accident by expert and experienced surgeons the interior condition of the joint was not accurately diagnosed, nor could it be known exactly without opening the joint. Had this patient been treated by non-operative procedure or by any operative procedure that did not recognize and correct the injury, the patient would have been condemned to permanent crippling of the limb, and all the limitations which that implies. Whereas, by the open method of suture he was given the almost perfect joint above described. The benefit of the operation was so great that it is safe to say that were the bone now refractured and treated by any method the result, even after this accident, would be better than if he had been treated in the first instance by any other method of operation, though no refracture ever took place.

The case further shows the scope of the method of suturing. Soft sutures were accurately and easily passed through unlike structures and the hand was able to recognize the unusual hardness of the bone. I have observed that in fractures by direct violence the bone has been harder than in those broken by muscular action.

Case IX.—Simple fracture of the patella from direct violence; wired on the ninth day under irrigation with 1 to 2,000 bichloride of mercury solution; laceration not through the whole thickness of the capsular structures; fibrous tissue infolded upon the fragments; drainage-tube removed on the fourth day; primary union; passive motion on the sixteenth day.

Refractured at the end of two months; wired again in twenty-four hours under irrigation with 1 to 2,500 bichloride solution; slight infolding of fibrous tissue upon the fragments; adhesions in the synovial sac; drainage-tubes removed on the fourth day; primary union; passive motion at the end of two weeks; bony union of the patella, with ultimate perfect recovery of function of the joint.

W. B——, eleven years of age, a school-boy, was admitted into Bellevue Hospital, January 1, 1885. The patient has always been healthy. While playing on top of a coal-bin he was startled by one of his playmates and fell off, striking his right knee on the sharp edge of the curb-stone. Without knowing that he had broken a bone he attempted to walk after the accident but fell down. Soon afterward he was admitted into the hospital.

Examination shows that the right knee is considerably swollen and tender and that the patella is broken transversely at its middle, with one inch separation of the fragments, which can be brought together without difficulty and give crepitus.

The limb was bandaged to a posterior splint and an ice-cap was applied to the knee.

January 5th.—The ice-cap was removed and the knee was strapped with strips of lint wet with lead and opium wash.

January 10th.—The knee is less swollen.

The operation of wiring was performed under continuous irrigation with a warm solution of 1 to 2,000 bichloride of mercury. The transverse incision through the skin revealed the subcutaneous aponeurotic expansion intact, giving at first the impression that the capsular structures were not lacerated. The incision being somewhat extended toward the outer aspect of the joint showed a perforation of the subcutaneous tissue by the sharp outer angle of the upper patella fragment, and upon deepening the cut the deeper structures were found to be extensively lacerated. The upper half of the bony surface of both fragments was covered by the infolded fibrous tissue, thus preventing the bony contact necessary for osseous union. This tissue was elevated with a sharp spoon and carefully preserved to cover the line of approximation of the fragments. A drainage-tube was inserted at the place of election.

The operation lasted one hour and a quarter; the dressing occupied fifteen minutes.

January 14th.—The dressings were removed under irrigation. There was about two drachms of sero-sanguinolent discharge upon the dressings. There is, apparently, primary union along the incision in the skin. There is a superficial excoriation of the skin beneath the protective, caused by the bichloride, elsewhere it is healthy. The drainage tube was removed and the limb re-dressed.

January 16th.—All pain about the joint has disappeared.

January 24th.—The union of the wound is complete, with the slight exception of a small spot of granulations at the inner end of the transverse incision. The joint is normal in size and there are no evidences of inflammation. The fragments are in good position and apparently united. The slight excoriation was dressed and the leg placed upon a posterior splint.

The highest temperature was 101.5° F. the evening after operation and sank to normal on the fifth day.

January 26th.—The splint was removed and passive motion exerted, moving the leg through ten degrees. The splint was reapplied.

January 27th.—The leg was moved through about twenty degrees.

January 28th.—All dressings have been dispensed with and passive motion is practised daily with great care and with a progressive increase in the range of movement.

January 29th.—The leg can be moved through twenty-five degrees.

February 3d.—It moves through forty-five degrees.

February 10th.—He has motion through an arc of sixty degrees.

February 20th.—The leg can be bent to nearly a right angle with the thigh.

February 28th.—The leg can be moved freely and without much pain to a right angle with the thigh.

Refracture, March 7th.—The patient, who had acquired motion of the leg to a little past a right angle with the thigh, was pushing a chair before him with his hands, and at the same time practising flexion of both legs, when the chair suddenly slipped away and he fell upon his knees, forcibly bending his legs under him. He realized at once that he had refractured his patella, on account of

the marked depression in the line of the transverse incision. He was immediately put to bed.

Upon examination the joint was found much swollen. The separation of the patella fragments apparently along the line of former fracture was made out. The fragments, which were about one-half an inch apart, could be brought together with crepitus. A posterior splint was applied to the limb and an ice-cap to the joint. After a few hours the ice-cap was removed and the knee was well strapped with lead and opium wash.

Second operation, March 8th, at 3 P.M., twenty-four hours after refracture, under irrigation with a warm solution of 1 to 2,500 of bichloride of mercury.—The knee was now of nearly its normal size. The fragments were felt to be about half an inch apart, and a protruding end of the wire could be felt just beneath the skin on the outer aspect of the joint. The incision to open the joint was begun a short distance below the cicatrix on the inner side of the joint, and, extending parallel to it, crossed it at the middle, where it was carried above and then parallel with it to the outer side of the joint. The periarticular tissues were found torn, although not so widely as in the first accident. About two ounces of blood-clots were washed out from between the fragments and from beneath the undermined cutaneous tissues over the anterior surface of the joint. It was now clear that the compressing bandage had diffused the blood in pouches torn beneath the skin. The wire had untwisted and been pulled through the drill-hole in the upper fragment. Its end was lying between the fragments and directed to the outer aspect of the joint. It was clean and bright, and so firm in the lower fragment, where its position had apparently not been disturbed, that heavy pliers were necessary to withdraw it. Both broken surfaces were somewhat overlapped by infolded fibrous tissue, but not nearly so far as in the first fracture. The extent of the synovial cavity was considerably lessened, both by a general contraction and by adhesions which had in great measure obliterated the synovial pouch, extending upward beneath and beyond the upper fragment. The surfaces of the fragments presented no traces of a ligamentous union, but were rough and bony. The small adherent blood-clots were lightly scraped away and the infolded fibrous tissue lifted. The fragments were brought together by a single wire. The cavity formed by the undermining of the skin upon the anterior aspect of the joint was drained by four tubes passed through the counter-openings; a tube was inserted into the joint as usual. The capsular structures were less distinct than in the first operation, and only a few stitches were used to close the rent in them. The operation lasted one hour. In dressing the wound, the protective silk was omitted. There was very little pain after the operation.

March 12th.—The dressings were removed under irrigation. There was a small amount of sero-sanguinolent discharge surrounding the ends of the drainage-tubes. The line of the skin incision had apparently healed by first intention. The tubes were removed and the limb was redressed.

March 21st.—The line of incision has all healed, except at the point of convergence of the cicatrices, where a knot in a catgut suture had pressed, and caused a small and very superficial slough. The places of emergence of the drainage tubes presented granulating spots. The limb was re-dressed and placed in the wire splint. The temperature rose to 100.6° F. the night after the operation, but the next day it was normal and never rose again.

March 23d.—There is a granulating spot the size of a ten-cent piece at the place of emergence of the lower and inner drainage-tube and a smaller one at the site of the slough above mentioned.

Passive motion was begun and movement of the leg to angle of twenty degrees was easily obtained without the use of any considerable degree of force. Passive motion is ordered to be practised daily.

March 30th.—There is motion to an angle of forty-five degrees. Passive motion renders tense the tendon of the quadriceps extensor.

May 1st.—The leg moves through an arc of fifty degrees.

January 25, 1886.—The wired patella is somewhat hypertrophied and indistinctly notched at its sides in the line of fracture. The wire can be obscurely felt through the skin, but has never produced any irritation nor discomfort. The patella can be moved as freely laterally as the opposite one. The range of flexion and extension of the injured limb and the function of the joint are in every respect as perfect as in its uninjured fellow.

November 1, 1886.—The patient was exhibited to the class at the Bellevue Hospital. His knee-joint remained in perfect condition.

February 10, 1890.—The joint remains in perfect condition and has never exhibited any weakness. He was this night exhibited at a meeting of the Surgical Section of the Academy of Medicine.

Remarks.—The conditions present at the first operation tend to confirm the explanation of MacEwen of the mechanism of the infolding of the torn fibrous structures.

The sharp spicular anterior edge of the upper fragment had caught in the elastic fibrous tissues and opposed their retraction. The lesser amount of infolded tissues found at the second operation is explained by the fact that the fibrous tissues were less elastic at the time of the re fracture.

This case illustrates the danger attending the use of the permanent wire suture, for had the refracture occurred when the patient was beyond the reach of skilled attendance, his limb and life might have been imperilled.

Had the fragments been sutured in the first instance by soft suture, the patient, after the refracture, would have been in a better attitude toward any non-operative method of treatment than he would have been had the fragments not been primarily sutured by the open operation.

The case further shows that the adhesions in the joint do not in themselves prevent the ultimate recovery of perfect function.

(To be continued.)

A CASE OF PARALYSIS OF THE SUPERIOR OBLIQUE CURED BY TENOTOMY OF THE SUPERIOR RECTUS OF THE SAME EYE.[1]

By DAVID WEBSTER, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC AND IN DARTMOUTH MEDICAL COLLEGE; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK, ETC.

William C. McK——, aged thirty-three, bachelor, clerk, was introduced to me by my friend, Dr. George C. Jeffery, on January 1, 1889. He said his eyes began to give out while working by gaslight in the latter part of 1887. In January, 1888, he selected glasses for himself [$+\frac{1}{60}$] at an optician's, and they gave him some help. In November, 1888, he consulted Dr. Jeffery, who advised him to lay aside his glasses, and he, after that, got along quite as well without them. He complains that his eyes seem to be "out of gear." He frequently becomes nervous and excited, and then his eyes are worse. He holds his head tilted to the left in order to avoid diplopia. In 1877, he had a chancre which was followed by various secondary symptoms: R. V.$=\frac{20}{20}$; Hm. O. 25 D. L. V.$=\frac{20}{20}$; $\frac{4}{5}$ with + O. 75 D.

Ophthalmoscope shows no lesion; physiological excavation of both optic disks, with pulsation of the retinal veins. On looking directly at a candle flame twenty feet distant the patient saw double images. These images were fused by prisms 5 base down and 8° base out over the left eye. The images become farther apart as the patient looks down. The patient was seen again on Jan-

[1] Read before the Ophthalmic Section of the New York Academy of Medicine, May 21, 1890.

uary 4th, and the following glasses were ordered for constant use: Rt. +O. 25 D. S. Lft. +O. 50 D. S. prism 3° base down. He was also put upon iodide of potassium in increasing doses.

January 14th.—The patient says the glasses rest his eyes and prevent "that tired feeling," but in order to see a thing distinctly with them he has to look straight at it. Advised to continue the glasses and the iodide.

February 1st.—Is taking 100 minims of the saturated solution of iodide of potassium three times a day. Gets along well with his glasses and is gaining flesh.

February 16th.—Is getting along about the same. To lessen the dose of iodide potas. by 5 minims every third day.

May 16th.—Stopped the iodide the latter part of April and has taken no medicine since. The paralysis of the left superior oblique remains unchanged, but he gets along very comfortably with his glasses.

October 3d.—The patient says that he has been having "the blues" without any sufficient cause. Latterly his head hasn't felt good, but he has not had what you would call a real headache. His eyes are not as strong as they were, and he often fails to see things correctly at first glance. He complains that he is getting more and more nervous and weak, and is entirely unfitted for business. A prism of 8° base down over left eye is now required to level up the double images. A tenotomy of the left superior rectus was advised.

November 1st.—The patient came to have the tenotomy performed. Immediately before the operation the double images were united by a prism of 9° base down, over the left eye. Immediately after the tenotomy of the left superior rectus, which was done under cocaine, the images were blended by a prism of 1° base down over the left eye. Five minutes later he was tested again, and it was found that a prism of 1° base up over the left eye was necessary to correct the diplopia.

November 2d.—The patient is troubled with diplopia which he fails to correct by tilting his head. A prism of 2° base up over the left eye is now required to cause the images to blend.

November 4th.—The patient complains that "everything is all astir and double." In the street a horse and wagon are double, and the upper one seems as though it were going up a hill. A prism of 6° base up over left eye fuses the images. It was now evident that the over-effect of the tenotomy was increasing and, without further surgical interference, would be permanent, so that "the last state of the patient would be worse than the first." We therefore again cocainized the eye, opened the wound, caught up the free end of the tendon which had retracted too far, and stitched it to the episcleral tissues on the corneal side of its former insertion. This stitch was drawn gradually tighter until the double images on the vertical plane were fused, and until the double images, produced by prisms placed horizontally before either or both eyes, were in a horizontal plane.

November 5th.—Patient has been comfortable since the readjustment of the muscle. No hyperphoria of either eye.

November 8th.—The patient has single binocular vision which is kept up with a red glass over either eye. Removed the stitch.

November 12th.—The patient complains that for the last few days he has had an uncomfortable feeling in his left eye, as though an eyelash were inverted. Inspection shows a slight abrasion of the corneal epithelium.

Orthophoria; sursumduction R. 2°; L. 2°; abduction 4°; adduction 4°.

Homatropine solution was dropped into the eye and a bandage applied.

November 13th.—Abrasion healed. Orthophoria, abduction 8°, adduction 9°.

January 1, 1890.—The patient comes to my office to report himself "as well as he ever was in his life." He needs no glasses, carries his head erect, has no confusion of vision, and has no more of that tired feeling. The prism tests show no insufficiency of his ocular muscles (orthophoria).

There are some interesting points in this case. In the first place, as the paralysis was due to syphilis, we expected to give relief by a thorough course of iodide of potassium. But although doses of nearly three hundred grains a day were taken daily for several weeks, and large doses for several months, no result was obtained so far as his eyes were concerned. In the second place, we may say that the completeness of the relief following the operations upon the superior rectus was very remarkable. There remained no diplopia in any part of the field, and the nervous symptoms, which had almost entirely incapacitated the patient for work, disappeared simultaneously.

Some time in 1888, Dr. H. Knapp reported a case to the Ophthalmic Section of the New York Academy of Medicine similar, in many respects, to that reported above. So far as I know, Dr. Knapp's case, which is not yet in print, is the only case besides my own treated in this way.

In Vol. IV. of the *Archives of Ophthalmology*, the same author publishes three cases in which he performed tenotomy of the superior or inferior recti for paralytic squint, but these were all complicated cases, other muscles being involved. They were:

"1. Tenotomy of the upper and lower recti of the same eye for paresis of the upper rectus.

"2. Tenotomy of the external rectus of both eyes, and the inferior rectus of the left eye, for strabismus and diplopia.

"3. Strabismus, sursumvergeus, improved by tenotomy of the superior rectus with a suture, increasing the effect, through the lower lid; cured by advancement of the inferior rectus."

Clinical Department.

A CASE OF FRACTURED PELVIS AND ITS TREATMENT.

By E. J. KEMPF, M.D.,

JASPER, IND.

As there is something in knowing just how to use a good thing, I concluded to make a report of a case of fractured pelvis and its treatment.

F. G——, a coal miner, was shovelling coal in a room of a coal mine, when a pillar gave way and the whole roof, weighing several tons, came down on him. The miner was crushed down by the side of a pile of loose coal. His comrades succeeded in getting him out in a few minutes.

I found him on an improvised cot, near a red-hot stove in a shanty. He was conscious, he suffered intense pain in the pelvic region and in the back, his right leg was completely helpless, and he complained of being very cold. My patient was undoubtedly suffering from shock due to some internal injury. We removed his wet clothes by cutting them away, put on dry ones, gave him brandy and a dose of morphine, placed him on a feather-bed, and carried him to his home. I drew his water off with a catheter, and found that his bladder was all right. He had involuntary discharge of thin, bad smelling fæces.

The right leg was helpless, everted, and the least movement caused him great pain. Crepitus could be felt in the hip-joint. There was marked deformity over the right sacro-iliac synchondrosis. There was pain over the pubic articulation.

On the morning after the accident the patient had recovered somewhat from the shock; but as the least movement caused him great pain, and because the right leg gave the patient a great deal of trouble—due, no doubt, to the fracture extending into the acetabulum—I concluded to put the patient into a plaster dressing, which I

did in the following manner, with the assistance of Dr. J. P. Sall.

Two staples were driven into opposite walls of the room, and a common fifty-cent hammock was suspended therefrom. On the hammock I placed rolls of cotton, about four inches thick for the abdomen and pelvis, and two inches for the thighs. On this we placed the patient, who was enabled to steady himself by means of a rope hanging from the ceiling. A slit was cut in the cotton and in the hammock from the knees to the scrotum, and the cotton and the hammock were closely bandaged to the patient's abdomen, pelvis, and thighs. The application of the plaster bandages was made slowly and carefully.

The plaster dressing being completed, the patient was allowed to remain suspended for three hours, until the plaster had thoroughly hardened. The patient felt easier. He had an operation on his bowels, passed his urine into a long-necked bottle, and afterward took some milk and bread.

After the dressing had become firm, the patient was supported by four men, and the hammock was cut off just beyond the edge of the plaster, and the patient was placed on a feather-bed.

In order to be able to examine my patient and to watch for complications, I cut the plaster dressing open over the abdomen, and over each thigh. With a punch I made holes on each side of the slits, so that they corresponded to each other, and then I laced the plaster dressing.

After six weeks I cut off the thigh pieces, and my patient went about on crutches with the hip-corset. He made a good recovery, with some deformity near the right sacro-iliac articulation.

This apparatus is easily applied in the manner described, and one can take his time while at it, and skilled assistance is not required.

It lessens the pain and discomfort. It lessens the danger of abscess, and it admits the inspection of the patient whenever necessary. It can be made use of in fractures of the spine. But in such cases the patient should be placed on his belly when put into the hammock, and the dressing should extend above the shoulders. Slits can be made in the hammock for the arms, and extra cotton should be put under the shoulder-joints, or rather in the axillæ.

The hammock suspension-plaster-dressing is not original with me. It has been used before, but as far as I am aware not in the manner and for the purpose I have described.

ERYTHROMELALGIA.

By C. SEYMOUR, M.D.,

NORTHAMPTON, MASS.

In 1872 Dr. S. Weir Mitchell, of Philadelphia, described a case of vaso-motor neurosis that had hitherto eluded classification. He labelled the malady, erythromelalgia, a Greek compound signifying redness and pain, these symptoms being the expression of the disease.

Dr. Mitchell subsequently published in the *American Journal of the Medical Sciences* a fuller report of this interesting disorder, embracing five cases under his own observation, together with six cases collected from reports by such authors as Vulpian, Graves, and Paget, and which obviously belong to this peculiar neurosis. The limited number of cases of this disease heretofore recorded leads me to put on record the following :

Miss A. B——, aged forty-five, a teacher for many years, and a very intelligent woman. She has light florid complexion, blue eyes, is well developed and well nourished. Her mother was a nervous invalid, otherwise her family history is good. By constitution she is entirely free from that complex nervous condition which is termed hysteria ; but, seven years ago, her health became impaired from excessive mental application, and she had to relinquish work for two years, wrestling with neurasthenia. During this period insomnia was so persistent she was impelled to use chloral. This habit she continued even after health had been restored and her position as teacher had been resumed. For five years she has slept either with chloral or its recent congener, sulfonal.

In November, 1888, while out walking, she suddenly experienced a sharp, burning pain in the ball of the left foot. This pain rapidly increased, and, as she expressed it, "it was agonizing before I got home." On assuming the recumbent position the pain gradually subsided, and did not return till a week later, when she was attacked on the street as before. From that time, eighteen months ago, she has been incapacitated from walking, or even standing for any length of time. To persist in such an effort is to invite certain and severe distress in the sole of the foot, from which part it will extend so as to involve the dorsum and even the leg. She cannot even allow the foot to hang down without torture, and always sits with it resting upon a chair. With the foot in a horizontal position she is perfectly at ease.

The second peculiar feature mentioned by Weir Mitchell is strikingly marked in this case, namely, the venous congestion of the skin, or flushing. The entire foot, when pain is present, becomes swollen and assumes a dull, mottled redness, like erythema or roseola. Even at these times there is little or no tenderness on pressure.

The third marked symptom of this unique disorder is equally manifest here, viz., the effect of heat and cold upon the foot. Even when the foot is at rest in a horizontal position, warm coverings are intolerable, and the application of cold brings relief. She often bathes the foot in very cold water, even in cold weather, and frequently sleeps with it uncovered. It is far more troublesome in summer than in winter.

The etiology of this disease is obscure, says Dr. Mitchell, but in this case it is manifestly the outcome of a depleted nervous system, aggravated by the long continued use of chloral and sulfonal. That the malady is intractable to medical treatment is demonstrated by the failure of able physicians, both here and in Boston, to relieve it, thus corroborating Dr. Mitchell's unfavorable prognosis of these cases. He says : "I believe that the group of cases described represent an unrecognized type of spinal or cerebro-spinal disorder, and that they may be found in the future to be associated with distinct lesions of definite regions. The mere fact of pain, with vaso-motor disturbances, does not, I think as yet, authorize me to attempt to localize the malady, and I prefer to resist the temptation to speculate in this direction without sufficient grounds."

Proofs of Bacillary Migration from Blood-vessels.—Dr. Latis, of Modena (*Centralblatt für Allgemeine Pathologie und Pathologische Anatomie*), reports experiments tending to show that the walls of the blood-vessels are so modified by the virus of anthrax as to readily lead to diapedesis ; and hence to infer that direct transference of the disease from the maternal to the fœtal organism is possible, without assuming (as has been done) the necessary antecedent condition of placental hemorrhage. He introduced into the peritoneal cavity of guinea-pigs small portions of elder pith thoroughly sterilized by boiling, and then inoculated the animals with anthrax. Subsequent microscopical examination of sections of the pith showed it to contain anthrax bacilli as well as blood-corpuscles. In others he excited keratitis, and detected the bacilli in the corneal epithelium, and occasionally in the plasmatic channels. By varying the time after infection at which the animals were destroyed, he found that, in the mesentery the first effect was a migration of leucocytes, which gradually increased, and which was followed later by an invasion of bacilli and red corpuscles. He also found that when cinnabar was injected into the jugular vein during these experiments, its particles appeared together with the bacilli in the elder pith or mesentery.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 7, 1890.

THE TREATMENT OF EMPYEMA.

THE course of empyema depends so much upon the individual peculiarities of each case, its etiology, the age, strength, and diathesis, that no hard-and-fast rules can ever be laid down for its treatment. But it is a disease which always calls for interference on the part of the physician, and hence it is one upon which much fruitful study can yet be made. The recent discussion of this topic before the German Congress of Internal Medicine, at Vienna, is of especial interest, because it shows the views of many leading European physicians and surgeons regarding treatment. The main point at issue in the debates in question was that of the extent and character of surgical interference; for it is agreed by all that, except in rare cases of small sacculated empyemas, some such interference is indicated.

Professor Immermann, of Basle, who opened the discussion, stated first of all that the pus must be evacuated by operation, and next, that simple aspiration will not answer except in small empyemas, which would become absorbed of themselves. The plan recommended by Bulau, of permanent aspiration by inserting a trochar connected with an elastic tube which leads into an antiseptic solution, was spoken of most favorably. Immermann collected statistics of 49 complete cures out of 57 cases. It is not suitable, however, for cases of inexpansive lung. pyo-pneumo-thorax, or pulmonary fistulæ.

Dr. Schede, of Hamburg, took the surgeon's view of the matter and advised the radical operation, *i.e.*, resection of a rib. Bulau's operation he thought much less safe than resection. The site of incision should be as low as possible. It was best to incise about six centimetres of the ninth or tenth rib.

Dr. Curschmann, of Leipsic, had treated all cases in the past ten years by aspiration-drainage (Bulau's method). Among 73 cases, eighty-nine per cent. were cured and 6 died. Professor Leyden spoke favorably of Bulau's method.

Dr. Ewald, in 1874, had collected statistics in Frerich's clinic of 109 serous and 46 purulent cases, and had then concluded that, of 1,000 cases, 928 do not get well with simple puncture, while 528 are cured by the radical operation. The results of surgery to-day are much better than that. In the present year he had, with Köster, operated with the double incision in 9 cases, with 1 death, from rapid tuberculosis. The operation was done as soon as the nature of the case was proved. The objections arising from old cases would be obviated if early interference were the rule.

Professor von Ziemssen (Munich) had for ten years past treated all empyemata by incision and rib resection, and was perfectly satisfied with this method.

Dr. Mosler, of Greifswalde, brought up the important point of prophylaxis. For the purpose of preventing serous effusions becoming purulent, he took measures against the invasion of streptococci and staphylococci by the mouth, nose, and pharynx. After the operation he washed out with boracic acid, and then injected iodoform and glycerine.

Dr. Runeberg, of Helsingfors, treated all empyemata by rib resection, and did not wash out. He had thus dealt with 63 cases, of which 2 were still under treatment. Two were manifestly tuberculous, 10 were due to pulmonary gangrene, 49 were simple empyemata. Of these latter 46 were completely healed; in 2 fistulæ remained; 1 case died from erysipelas. The average duration of treatment was forty-eight days.

It will be seen that the opinions were mainly divided upon the question of aspiration-drainage or resection. No one seemed to advocate the method very commonly employed in this country, viz., simple incision and drainage. Excellent results are obtained by this plan. All were agreed upon the fact that injections were useless.

THE SULPHUR FUMIGATION HUMBUG.

WE observe that Boards of Health continue to recommend the fumigation of wards and rooms with sulphur, as a means of disinfection. An additional and highly esteemed point in technique is now given, viz., the preliminary moistening of the walls and furniture.

It is surprising that scientific bodies continue to send forth these disinfection pamphlets. There is no evidence at all that sulphur fumes disinfect the rooms in which they are produced, or do any good whatever, except impress the laity with the bituminous resources of sanitary science, and create with them a false sense of security.

We trust that before many years this ancient fetich of alcohol and roll-sulphur, "3 lbs. to a room 10 feet square," will be stored away with the other fallen idols.

A NEW SOURCE FOR PROTECTIVE VACCINES.

SEVERAL recent studies upon the products of the growth or activity of pathogenic bacteria show that among these products are certain poisonous proteid bodies. These substances possess in some cases the same pathogenic property as in the original micro-organism. We have, therefore, as the result of microbic activity, not only ptomaines which are alkaloids, but a class of bodies which react like albumins.

This latter class has been called pathogenic albumoses, or "tox-albumins." Mr. E. H. Hankin, of Cambridge, has obtained such an albumose from anthrax cultures, and Mr. Cartwright Wood has used it successfully as a protective vaccine. Brieger and Fraenkel have studied the diphtheria bacillus of Löffler, and have obtained a toxic albumin from it. They found that it produced no ptomaine.

They obtained similar bodies from cultures of the specific microbes of typhoid, cholera, and tetanus, and of the staphylococcus pyogenes aureus, and in each case the bodies possessed definite pathogenic properties. The details given are not numerous, but it is of interest to note that the proteid isolated from cultures of staphylococcus appeared to give rise to the formation of pus differing from normal pus only in being completely devoid of micro-organisms.

The practical importance of these discoveries lies in the fact that it may be possible, through the use of these new bodies, to obtain protective vaccines for various diseases.

News of the Week.

The Pasteur Institute has now (for the first time since antirabic vaccination has been practised) published complete statistics of the results of the Pasteur treatment for hydrophobia. From January 1, 1886, to December 31, 1889, 7,393 persons bitten by mad dogs have been treated; 53 of these have died—a proportion of 0.67 per cent. The proportion of deaths when the treatment is not adopted is 15.90 per cent.; consequently, among the 7,893 patients of the Pasteur Institute, 1,265 would have died had not the Pasteur method of treating hydrophobia been carried out.

Virchow's Seventieth Birthday.—The friends of Professor Virchow look forward to the celebration of that eminent man's threescore and tenth year on the 13th of next October. Dr. Waldeyer is at the head of the movement to make the event memorable, and may be addressed by any pathologist, anthropologist, or liberal compatriot, now in America, who may feel impelled to contribute to its success. There are probably not fewer than a thousand physicians in this country who have been students of Virchow's at one time or another during the past thirty years.—*New York Medical Journal.*

A Policlinic in Paris.—A Policlinic (with an i) has been recently established in Paris, after the model of the Policlinics of Vienna and Berlin.

Sir Morell Mackenzie is said to have been engaged by an American manager to deliver a series of lectures in this country during the coming fall and winter. He is engaged for at least twenty lectures, at the rate of $500 per lecture.

Alumni Association of the Mount Sinai Hospital.—An association of the alumni of this hospital was organized on May 16th, the objects of the society being both social and scientific. Meetings will be held on the last Tuesday in January, May, and October of each year. At the first meeting the following officers were elected: *President*—Alfred Meyer; *Vice President*—Henry Stark; *Secretary*—H. J. Schiff; *Treasurer*—A. H. Friedenberg. Information concerning the conditions of membership, etc., may be obtained by addressing the Secretary, Dr. Schiff, No. 235 East Seventy-eighth Street.

The Austin District Medical Society will hold its eleventh quarterly meeting in Austin, Tex., on Thursday, June 19th. Dr. F. R. Martin, of Kyle, is President, and Dr. T. J. Bennett, of Austin, Secretary and Treasurer.

Dr. Frank Baker, of Washington, has been appointed curator of comparative anatomy in the National Museum

The Maine Medical Association will hold its thirty-eighth annual meeting at Portland on Tuesday, Wednesday, and Thursday, June 10, 11, and 12, 1890.

Naval Delegates to the International Congress.—Medical Director Albert L. Gihon, U. S. N., in charge of the United States Naval Hospital, New York, and Medical Director David Kindleberger, U. S. N., have been appointed by Secretary Tracy to represent the medical department of the Navy at the International Medical Congress.

A Compliment to Pasteur.—A number of British and American admirers of M. Pasteur, including the Prince and Princess of Wales, have presented him with an album containing their autographs.

A Party of Seven Persons from St. Joseph's, Ill., have come to this city to be treated at the Pasteur Institute. They had been bitten by a mad dog.

Dr. Otto Kopetschy, of Jersey City, died on May 29th, and was cremated at Fresh Pond, L. I.

The Man with the Cracked Ear.—Dr. Wagner, of St. Johann-Sarrebruck, reports the case of a man who for a year and a half suffered from most unpleasant cracking noises in his left ear. These occurred every five or six seconds, and could be distinctly heard by a person standing twenty centimetres away. The patient had no deafness or inflammatory trouble, but examination of the drum showed a split in it, through which air was forced with each act of deglutition.

Dr. Elliott Coues, of Washington, has been expelled from the Theosophic Society, because he showed up the trickery of Madame Blavatsky.

Bequests to Hospitals.—By the will of the late Miss Mary E. Edson, the sum of $10,000 is left to the New York Cancer Hospital; $5,000 to St. Luke's; and $5,000 to the Woman's Hospital.

Crane Surgical Operating-room.—The sum of about five thousand dollars has been given by a daughter of the late Dr. Crane, to build and equip a surgical operating-room at Bellevue Hospital.

A Firm of Opticians, in Philadelphia, have sent out circulars announcing that they have engaged the services of registered physicians, who in addition are ophthalmologists. They are able thus to examine all persons and fit them with glasses if necessary. They state that only ten per cent. of people applying for glasses need to be examined with the aid of mydriatics. The circular has created some excitement, and called out strong expressions of disapproval.

Aniline Dyes as Antiseptics.—In an essay entitled "Aniline Dyes as Antiseptics," Professor Stilling, of Strasburg, claims to have discovered antiseptics strong enough to kill bacteria in a concentration not injurious to the human body, and at the same time diffusive enough to spread wherever on a wounded surface suppurative micro-organisms exist. In the case of a man of seventy, the whole of whose left leg between the ankle and the knee was covered with ulcers which would not heal, Professor Stilling sterilized them all in a few days with the best result.

Army Delegates to the International Congress.—Drs. Charles H. Alden and John S. Billings have been detailed by Secretary Proctor as delegates to the International Medical Congress in Berlin.

Physicians Arrested.—Scarlet fever and diphtheria are very prevalent in the town of Highlands, near Denver, Col., and the citizens are becoming almost panic-stricken. Among other measures taken to improve the health of the community and to prevent further spread of contagion, warrants have been issued for the arrest of a number of physicians who have failed to report cases of diphtheria and scarlet fever occurring in their practice.

Arkansas State Medical Society.—The following officers were elected at the annual meeting of this Society, in Little Rock, on May 18th: *President*—Dr. J. A. Dibrell, Jr.; *1st Vice-President*—Dr. R. N. Ross; *2d Vice-President*—Dr. J. L. Goree; *3d Vice-President*—Dr. J. A. Williams; *4th Vice-President*—Dr. J. B. Payne; *Secretary*—Dr. L. P. Gibson; *Assistant Secretary*—Dr. Joseph H. Leslie; *Treasurer*—Dr. A. L. Breysacher; *Librarian*—Dr. R. B. Christian. Hot Springs was selected as the next place of meeting.

The Medical Society of the County of Kings held a regular meeting in Brooklyn, May 20th, at which Dr. J. Fuhs read a paper on "Spasmodic Urethral Stricture." Drs. L. Bolton Bangs, of New York, and H. W. Rand, of Brooklyn, took part in the discussion. This was followed by a paper entitled "Report of a Case. Was it Hydrophobia?" by Dr. A. Ross Matheson.

The Pathology of an Equatorial Forest.—Mr. Stanley waxes into pathologic eloquence in his description of the immense forest through which his party travelled for weeks. "I saw that some trees were many centuries old; some in the prime of life, with every fibre healthy; some glorious in youth and strength; some goitrous, warty, ulcerous, stunted, and unwholesome; some slaves of slaves strangled by rigid clutch of a pythonous parasite, the parasite in its turn bound firm with exceeding tension by a snaky creeper, and that also covered with lichen and moss; some with great sores exuding globules and pastils of gummy matter, the ants feeding on them like flies on pus; some old, ancient, palsied by a lightning-stroke—life, death, and decay all around as with us."

The Fifth District Branch of the State Medical Association held its sixth annual meeting in Brooklyn, May 27th. Dr. John Shrady presented a tribute to the late Dr. I. E. Taylor, and Dr. C. A. Leale read a memoir of Dr. C. S. Wood. Biographical sketches of Drs. L. H. Sayre, W. B. Eager, G. V. Skiff, G. L. Sutton, and Edwin Webb were read by title. A paper entitled "Observations on Rheumatism, especially as involving the Tonsils," was read by Dr. William Henry Thayer. Dr. H. Ernest Schmid, presented "Some Personal Observations upon the History and Claims of Hypnotism and its Employment in certain Diseased Conditions." Dr. George Tucker Harrison read a paper on "Ectopic Gestation, its Diagnosis and Therapeutics," and Dr. J. W. Gleitsmann, a paper on the "Surgical Treatment of Cough in Diseases of the Upper Air-passages." Dr. T. H. Manley showed several patients upon whom he had operated for cure of hernia. The Executive Committee for the ensuing year was then chosen and the Society adjourned to meet in Kingston, July 22, 1890.

A State Medical Journal.—At the recent annual meeting of the Arkansas State Medical Society, in Little Rock, a resolution was adopted to establish a medical journal, to be conducted by a committee of the Society on the same plan as the organ of the American Medical Association.

Another Remedy for Sea-sickness is put forward by Mr. Charles W. Hamilton, Surgeon R. N. (*British Medical Journal*). It is the seeds of the kola nut, of which half a drachm to a drachm are to be chewed slowly.

The Congress for Internal Medicine.—A paper which attracted much attention was one by Dr. Romberg, of Leipsic, on "The Innervation of the Heart." In connection with Dr. His, studies were made upon the embryology of the cardiac nerves (*The Lancet*). The first appearance of cardiac nerves could be detected in the fourth week, when ganglia, detached from the sympathetic chain, migrated into the heart. In the second and third month the deep and superficial aortic plexuses were formed, while the ventricles remained without any ganglia. Therefore the cardiac ganglia must be regarded as offshoots of the sympathetic ganglia, and as the latter belong to the system of the dorsal roots of the spinal cord, the cardiac ganglia are not motor but sensory nerves, and they cannot represent an automatic cardiac centre, as has previously been assumed. This view, based on embryological investigations, is corroborated by well-known physiological observations—for example, by the fact that the heart of the embryo beats rhythmically long before it possesses nerves or ganglia. The experiments made by Woolridge in this direction were also mentioned by the lecturer. Dr. Romberg believes that the heart muscle is the automatic motor force of the circulation of the blood without being stimulated for this purpose by the nervous elements. According to this view, the pathological study of the cardiac muscle becomes still more important. In pathological changes as well as in experimental toxicology the state of the heart *muscle* must be taken into consideration. To the cardiac ganglia the lecturer ascribed a reflex influence by which the vagus and accelerator nerves are brought into action. Professor Senator read a paper on "Chronic Bright's Disease," in which he dwelt chiefly upon its therapeutics (*British Medical Journal*). As regards medicines, stimulants were to be avoided, and astringents, which theoretically should diminish albuminuria, had not the desired effect. Experiments with benzoic acid, arsenic, ichthyol, and other remedies had also failed; the same might be said of iron preparations, which had been given for the anæmia. Parenchymatous nephritis might come to a standstill at any stage, and disappear, leaving more or less organic change. Professor Senator had seen recovery take place even after the disease had lasted two years, and Johnson even after three years. As regards diet, albuminoid substances should be avoided, and food ought to consist of fat and carbon hydrates. This should be continued for several weeks, or even months; the patient should be well nourished, but the food should be such that the kidneys were freed of albumin as much as possible. According to Voigt, 80 grammes of albumin, 30 grammes of fat, and 300 grammes of carbon hydrates had to be conveyed to the organism to keep up the equilibrium; the proportion of

the albuminoids to that of the carbo-hydrates ought to be one to four. But less than a half of the mentioned quantity of albumin would suffice; 50 grammes of albumin—equivalent to about 2 litres of cow's milk, or to from 8 to 10 eggs, or to 250 grammes of meat—was the lowest quantity required by the organism; this need not be exceeded if food free from nitrogen was taken in sufficient quantity. Many who were against the limitation of albuminoid food emphasized the necessity of giving strong food, which should ameliorate the condition of the blood. This gain of strength, however, said Professor Senator, could be obtained in another way, for instance, by the introduction of fat. The majority of practitioners were in favor of milk diet, and in most cases about two litres of milk were given daily. Professor Senator was no partisan of the milk cure, but he never entirely abandoned the use of milk, as it contained no irritating substances, and it had also a diuretic effect owing to the water it contained. Disturbances of digestion seldom formed a contra-indication; on the contrary, they were frequently improved by the treatment. In many cases buttermilk, and also koumiss or kefi, could be taken. Besides food the activity of the muscles played a great part, as albuminuria was augmented by violent exertion. Moderate motion was therefore recommended. Fresh air was very useful, and the patients did well even to lie in the open air. Baths and *frottement* were of some utility, as there was some relation between the skin and the kidneys. Alkaline muriatic waters, the various teas, the acetate and tartrate of potassium, etc., had a diuretic effect, and this was also true of digitalis, squills, and strophanthus, by augmenting the activity of the heart. Caffein was contra-indicated, as it also affected the nervous system. Acid diuretics were, of course, contra-indicated. A similar treatment was also indicated in the case of atrophic kidney, in which iodide of potassium was useful, as it partly diminished the arterio-sclerosis which was almost invariably present. Strong cigars should not be smoked. Change of climate was useful, and patients ought to go to Egypt, Lapland, India, etc. Professor von Ziemssen said that in parenchymatous nephritis, in the treatment of albuminuria, pharmaceutical preparations should be used only with precaution, otherwise the digestion might be much disturbed. Astringents were useless; iodide of potassium was of some use, and in some cases ergot was successful. During exacerbations of albuminuria, and particularly if there was hæmaturia, the patients should be kept in bed. Bartels affirmed that after several years' confinement to bed, combined with the use of diaphoretics, he had seen well-developed albuminuria perfectly cured. Of diaphoretics, hot air and steam baths were chiefly indicated, especially the former. Pilocarpin was beneficial, particularly in dropsy of long standing. Digitalis, squills, acetate of potassium, and the preparations of antimony were also useful. Caffein and theobromin were useful diuretics, and did not increase blood pressure. Calomel had no effect at all in renal dropsy. With regard to mechanical treatment, Professor von Ziemssen introduced capillary tubes into the asepticized skin, fixed them with salicylate wool, and allowed them to remain *in situ* for twelve hours. In the case of interstitial nephritis, the various causes, such as alcoholic and metallic poisoning, gout, and syphilis, furnished particular indications. In excessive blood pressure, bleeding was useful. In cardiac excitement, ice-bags and morphine were useful; and morphine and ice-pills were beneficial in vomiting. Uræmia was best prevented by digitalis and stimulants (camphor, alcohol). During the attack these drugs could be given by the rectum. In desperate cases arterial bleeding and transfusion could be resorted to. In fibroid liver mineral waters were not good. A sojourn in southern regions was of benefit.

The Medical Department of the University of Pennsylvania held its Commencement May 1st, and graduated a class of 117.

Stanley's Tribute to Surgeon T. H. Parke.—In a recent address by Mr. Stanley he said of Dr. Parke: "Surgeon T. H. Parke, A.M.D., was the latest of our volunteer officers who applied for membership in the expedition. He wrote with his own hand the terms of the agreement, the most comprehensive being 'loyal and devoted service' gratuitously. For some months he pursues his duties without attracting much notice from me; he is so quiet and unobtrusive. Finally, the increasing distresses to which we are subject increases the sick-list alarmingly. I am obliged to attend personally to the matter, which brings me more into contact with the doctor, and gives me better opportunities of observing his manner of work. Splinters pierce the feet through and through, ulcers break out like an epidemic, nostalgia creates a chronic sinking of the vital powers, hunger weakens them, dysentery saps their strength, fevers enfeeble them, and various accidents occur, and each has its victims. Natives wound with arrows, knives, and spears, and before many months I find that nearly all the men pass under the doctor's hands. His patients vary from twenty to fifty in number daily; for once anæmia has firm hold of the constitutions, and the circumstances which caused the sickness remaining unaltered, except from bad to worse, the doctor's task never lessens. For months he has devoted his skill, his time, patiently and uncomplainingly, and always with a charming interest in his cases, until I have at last one hundred and twenty-four, a full one-third of the expedition, unfit for further travel. I call the doctor, and explain to him, and say, "You have done well, I admit; but I wish more yet, if possible. Take these one hundred and twenty-four, and cure them. How you will do it, I do not know; but come this once. Every hour of the day give to them, see that their terrible wounds are dressed, that they have rations regularly, and that their food is cooked, etc. Though they were a terrible sight when I left them in his charge, in one month over eighty are in prime condition and fit for active service, and a few weeks later there are only five incurably sick." He adds that Dr. Parke twice saved Stanley's life. Dr. Parke has been awarded the Honorary Fellowship of the Royal College of Surgeons of Ireland, which has thus shown a prompt appreciation of his work. The Khedive has conferred on him the Third Class Medjidieh. The Royal Geographical Society, at the Royal Albert Hall on Monday, May 5th, presented him, through the Prince of Wales, in the presence of a brilliant audience, with a medal which had been struck in honor of the services rendered to the cause of science and humanity; and the British Medical Association will present him with their gold medal for distinguished merit.

Society Reports.

American Medical Association.

FORTY-FIRST ANNUAL MEETING.

Held at Nashville, Tenn., May 20, 21, 22, and 23, 1890.

(Continued from page 630.)

SURGICAL SECTION.

FIRST DAY, TUESDAY, MAY 20TH.

Concussion of the Spinal Cord and Brain.—DR. WATSON, of Jersey City, in his inaugural address, confined his remarks to the subject of "Concussion of the Spinal Cord and Brain," basing his remarks upon 141 experiments made upon animals. In 135 of the experiments the concussive force was received on the nates, and besides other traumatisms there were 11 cases of rupture of spinal ligaments and 10 of this number occurred at the sacro-vertebral articulation, and the other between the fifth and sixth cervical vertebræ. In 6 cases there were extravasations of blood into pelvic cavity, and in 5 cases ecchymoses in the psoas muscles. In the 4 cases of fracture 2 were in the lumbar region, and he believed that the concussive force exerts the greatest potency when applied to the nates while the body is maintained erect. He viewed the subject from the stand-point of the surgeon and not from that of the alienist. The anatomy of the column, its peculiar construction, the relation of the cord and nerves to the bony surroundings were briefly dwelt upon, the important differences between the encephalon and cord described. He discussed three questions bearing on the etiology of spinal concussion: 1. Are there any cases of this morbid condition arising from concussive force in which the functions of the spinal cord are temporarily disturbed, independently of any discoverable lesions? 2. Are any of the following pathological conditions, viz.: Punctate hemorrhage, hyperæmia, blood in the perivascular spaces of the gray matter, etc., ever produced by concussive force while the bony walls of the spinal column and the ligaments of the same remain in a normal state? 3. How, and by what sort of force, are these morbid conditions most frequently caused? The first question was answered in the negative.

In answer to the second question he stated that out of the 141 experiments, there were 46 in which pathological lesions occurred. In 20 of these post-mortem examination revealed a want of continuity in the spinal column, and from the experiments he believed that pathological changes in the cord may be produced by concussive force while the bones and ligaments remain in a normal state. The paper was discussed by Drs. Carpenter, of St. Louis; Murphy, of St. Paul; King, of Kansas City; Hoadley, of Chicago; Coyn, of Dakota; and Van Quast, of Kansas City.

Nasal Surgery.—DR. MERRIL RICKETTS, of Cincinnati, read a report of several cases of "External Surgery of the Nose," and presented photographs showing cases he had operated upon. The causes of the various deformities were given as syphilitic, malignant, tubercular, traumatic, and congenital. He believed no operations should be done until necrosis has ceased, and in all syphilitic cases proper medicinal treatment should be used. The methods of filling in lost tissue of the soft parts were described briefly, preference being given to taking a flap from the cheek, the arm, and the forehead in the order named. He preferred silk to catgut, and advised further trial of skin-grafting from tissues taken from the lower animals.

Continuous Side Stitch Suture.—DR. C. L. LEWIS, of New York, read a paper on, "The Continuous Side Stitch Suture." The methods already in use by most operators present three objections: 1. They are interrupted and do not hold the surface in close and even apposition. 2. The tension of each stitch is placed upon the width of a thread and in consequence liable to cut through. 3 (and by no means the least). The time required often jeopardizes the life of a patient.

This suture of course is recommended in suturing serous surfaces, especially the intestines.

The advantages of this suture are strength, time, facility of execution.

The doctor reported experiments performed upon ten dogs in which this suture was used. In all the cases but one resections of two-thirds of the calibre of the intestine were done.

The paper was discussed by Dr. Jennings, of Arkansas, and Dr. Shimwell, of Philadelphia.

Resection of the Cæcum for Carcinoma.—DR. N. SENN, of Milwaukee, read a paper entitled "Two Cases of Resection of the Cæcum for Carcinoma, with Remarks on Intestinal Anastomosis in the Ileo-cæcal Region." His conclusions were:

1. Resection of the cæcum for carcinoma can be done with a fair prospect of a permanent cure if the operation is performed before infiltration of the retro-peritoneal and mesenteric glands has occurred.

2. Ileo-colostomy with absorbable perforated approximation plates is the best method in restoring the continuity of the intestinal canal after excision of the cæcum.

3. The best material for approximation plates is decalcified bone preserved in an antiseptic solution.

4. Hygroscopic and indestructible or unabsorbable material should not be used in the preparation of approximation plates or rings, as the former may cause pressure-gangrene, and the latter may prove a source of danger by remaining permanently as a foreign body in the organ in which it has been introduced.

5. Ileo-colostomy without resection of the cæcum is indicated in cases of intestinal obstruction from inoperable carcinoma of the cæcum, irreducible invagination without perforation, or evidences of gangrene, and in cicatricial stenosis in the ileo-cæcal region not amenable to a plastic operation.

6. Scarification of the serous surfaces interposed between the bone plates is the most reliable means of hastening the formation of adhesions, and of shortening the process of definite healing.

7. Resection of the cæcum and ileo-colostomy, with or without enterectomy, should be done through a lateral incision, extending from near the middle of Poupart's ligament to a point half-way between the anterior superior spinous process of the ilium and the umbilicus.

8. Suturing of the serous surfaces, just beyond the margins of the bone plates, renders material aid in maintaining apposition between the serous surfaces which it is intended to unite, and furnishes an additional safeguard against fecal extravasation.

9. Anchoring of the approximated parts in the ileo-cæcal region with a mesenteric-peritoneal suture, should be done in ileo-colostomy, after resection of the cæcum.

SECOND DAY, WEDNESDAY, MAY 21ST.

Gunshot Wounds of the Abdomen.—DR. DAVID BARROW, of Lexington, Ky., read a paper with this title. He reported two cases which, with cases already reported, makes six laparotomies he has done for gunshot wounds of abdomen, with four deaths and two recoveries.

CASE I.—Male, fifteen years of age, shot in abdomen February 8, 1890, at 7 P.M., by a 32-calibre ball. Operation at 11 P.M. Wound was one inch and a half to left of and in line of umbilicus. Symptoms were shock, vomiting, hard and retracted abdomen, pulse rapid and weak, lower extremities flexed, and pain severe. A four-inch incision made in linea alba—first made and then enlarged to six inches, as more room was needed. Six perforations of gut were found, four in small and two in large intestine, which were closed by the Czerny-Lembert suture, using fine intestinal silk, and in one of perforations

of large intestine, on account of the great bruising, stitches were reinforced with omentum. Irrigation copious and thorough—glass drainage-tube used. Incision closed with silk. Duration of operation one hour and a quarter. Recovery.

Case II.—Male, thirteen years of age, wounded by a 32-calibre ball at 4 P.M. Operation at 8 P.M. Wound was two inches to right of and one inch below umbilicus. A probe was passed into the cavity; no shock, nothing indicating serious injury. A four-inch vertical incision, including bullet-wound, made, and it was found ball had passed downward to the right. Five perforations were found, two in ileum, three in cæcum, which were sutured by the Czerny-Lembert stitch with fine silk. Irrigation with boiled distilled water. Duration of operation half an hour; no shock after operation; no drainage. Patient did well for two days, then developed septic peritonitis and died at the end of three days. Post-mortem demonstrated all perforations completely closed; omission of drainage, probably, was the cause of peritonitis and subsequent death.

From an analysis of one hundred and twelve laparotomies for gunshot wounds of the abdomen the following conclusions were drawn:

1. Gunshot wounds of the abdominal cavity should invariably be treated by laparotomy. With the operation the mortality is 66.27 per cent.; without the operation more than ninety per cent. die. 2. It will be safer to always open promptly and cleanse the peritoneal cavity, even should the viscera escape injury. 3. Symptoms are unreliable, and the surgeon should never wait for them if the ball has penetrated the cavity. 4. In every instance mentioned when the operation has been greatly prolonged the patient died. 5. In extreme shock, rather than occupy much time in suturing the perforations, adopt the open peritoneal treatment, and trust to irrigation and drainage. 6. In destructive wounds of the intestines lateral anastomosis promises better results than exsection. 7. By utilizing omentum sometimes extensive wounds can be closed without too much diminishing lumen of intestine. 8. In liver wounds the hemorrhage must be controlled and peritoneal cavity cleaned. 9. The kidney must be removed if wounded and bleeding. 10. The hydrogen-gas test is only of use in demonstrating the closure of all the perforations, and should be used just before closing the abdominal incision. 11. Irrigation should always be copious and thorough. It is the best treatment for shock, diminishes the thirst, and is the best means of guarding against peritonitis. 12. The drainage-tube should rarely be left out.

The Radical Operation for Hernia in Infancy and Early Childhood.—Dr. Thomas H. Manly, of New York, read a paper on this subject. He gave the histories of seven operations for radical cure of hernia performed within the past four months, in and out of hospital, on patients from two weeks of age to seven years; the number was so small and the time so short that it was scarcely possible to state as to the permanency of the cure. However, he said that as all his patients rapidly recovered from the operation in less than half the time required in adults, and as in none could a truss be worn, he felt justified in operating. He said that though the major portion of hernial cases recovered under the truss in childhood, yet they almost invariably returned later. In four of his cases the herniæ were of congenital variety, and the testis with the intestine or omentum were adherent, and no truss of any kind was of any use. He ridiculed the pretensions of those who condemned operations for radical cure of hernia because of relapses, for he said that, exclusive of traumatisms, most all surgical operations were followed by a relapse of the condition for which the original operation was performed. He said no special operation could be advocated for all cases. The surgeon must be guided by the conditions existing and adapt his technique accordingly. Owing to the fact that in the first year of life the infant is constantly in prone position, such as is favorable to thorough solidification of the wound and to the changes of anatomical evolution occurring in early life, he strongly advised doing the operation at the earliest possible period after the protrusion was discovered.

Persistent Priapism.—Dr. W. T. Briggs, of Nashville, showed a patient who had suffered during the past year with constant priapism which no treatment had relieved. No cause was known for the trouble and all the other functions of the body were normal. Sexual intercourse only aggravated the condition, made him irritable, and did not relieve the priapism. The doctor asked for advice from any member of the Section, but all methods suggested had been previously tried.

The Value of Urethroscopy.—Dr. J. B. Dearer, of Philadelphia, read a paper on "The Value of the Leiter Incandescent Lamp Urethroscope in the Diagnosis and Treatment of Chronic Urethral Discharges." He described the instrument, which is made in three pieces, the handle, the lantern, and the urethral cannulæ or tubes. Owing to its simplicity it rarely got out of order, the only part needing replacing usually was the lamp, which soon became blackened, and could be changed by simply removing the handle and loosening the two small screws holding the lamp. Pictures were shown illustrating the lamp, and the different forms of batteries to be used mentioned and preference given to the Grenet or plunge battery.

The use of the instrument was most satisfactory with patient in the recumbent position on a table or couch of considerable height, with the knees bent over the edges and slightly separated. The largest possible tube should be used and great care taken not to induce bleeding, thus obstructing the field of vision.

The normal condition of the urethra as seen through the instrument was then described, and Otis' views endorsed that in most cases of gleet more than one stricture was present. By the use of the instrument the following varieties of chronic urethritis could be made out:

1. Simple chronic urethritis. 2. Follicular urethritis. 3. Ulcerative urethritis. Rarely were two of the above conditions met with in the same case, and without the aid of the urethroscope the exact pathological condition which is keeping up the discharge cannot always be made out.

Four cases were reported and drawings shown of condition of urethra as seen through the instrument, and especial attention called to some causes of failure in curing cases of stricture operated upon by divulsion and which he believed to be an argument in favor of internal urethrotomy, namely tabs or teats of mucous membrane which have been separated at the time of divulsion; and by bougieing, the usual after-treatment, the union of these tabs to the surface from which they were torn has been prevented.

Supra-Vaginal Hysterectomy.—Dr. Howard Kelly, of Baltimore, read a paper upon "Supra-Vaginal Hysterectomy, or Hystero-myomectomy, with Suspension of the Stump in the Lower Angle of the Wound." He limited the operation to cases conceded most favorable for operation—those in which there exists naturally, or in which it is possible to form, a pedicle below the tumor masses, and not atypical cases, in which pan-hysterectomy is called for. The question of the best method of forming a pedicle when the broad ligament is choked with fibroid masses was also not discussed. Operation was discussed in seven steps.

1. Long incision in linea alba, necessary to deliver the tumor from the abdomen. 2. Elevation of tumor until pedicle is brought into view—tying the broad ligament structures until a pedicle is formed and rubber ligature applied. 3. Cutting away the tumor above the rubber ligature by first splitting the peritoneum high up, and then cupping out the upper face of the stump. 4. Closure of raw face of stump by uniting the opposite sides by a continuous buried suture of catgut, drawn tight to

check hemorrhage. 5. Cutting away the rubber ligature and securing any bleeding points. 6. Closure of abdominal incision down to the stump. 7. Dressing the wound. This was done by packing under the edges of the skin over the now suspended stump some antiseptic gauze; then over the whole a large square of gauze, in which there is a small slit, is placed, and then the long ligatures uniting the peritoneal lips of the stump are pulled through and grasped in the bite of a pair of long Keith's forceps laid horizontally to the body.

The advantages claimed for the operation were: Hemorrhage is not dangerous when it occurs, as it is under control, and sepsis cannot get into the abdominal cavity, and the facility of attaching the pedicle in the lower angle of the abdominal wound, especially if short.

Fractures in Children.—Dr. Edward Martin, of Philadelphia, read a paper, the result of a critical study upon over one thousand cases of fracture in children under twelve years of age. He stated that, contrary to general authority, fractures of the radius were most frequent, and that of these Colles's fractures were not so commonly found as in adults; next in order of frequency came fractures of the humerus, then fractures of clavicle and femur.

Fractures in children were peculiar in the fact that there was usually little or no displacement, due to thickened periosteum and slight muscular power. Greenstick fractures were always due to rupture of bony fibres, except in cases of rickets, when true bending might take place. Epiphyseal fractures were exceedingly rare, though injury near the epiphyseal line was common.

Diagnosis at times difficult. Treatment must be such that the patients could not escape, yet they could not be applied tightly. Prognosis always good.

Peroxide of Hydrogen.—Dr. Robert Morris, of New York, read a paper on "The Peroxide of Hydrogen." He urged strongly the use of this material in all cases where pus was present, and believed it superior to any other drug or compound for this purpose. He had used it largely, and with the most gratifying results.

Third Day, Thursday, May 22d.

Early Abdominal Section.—Dr. J. G. Carpenter, of Stanford, Ky., read a paper entitled "A Plea for Early Abdominal Section in Intestinal Obstruction."

He believed the best time to operate was as soon as the diagnosis was made, and before complications set in, and quoted the views of many surgeons to support the above. He advised the use of Senn's test, and condemned the use of opium in cases of intestinal obstruction. He believed that by Senn's intestinal anastomosis, lateral apposition, lateral implantation, intestinal exclusion, and Senn's modification of Jobert's operation by circular enterorrhaphy, the mortality of intestinal obstruction would be lessened in the future.

Election of Officers.—The following officers for the ensuing year were then elected: Dr. McGraw, of Detroit, *Chairman;* Dr. J. B. Deaver, of Philadelphia, *Vice-Chairman;* Dr. W. A. Davis, of Alabama, *Secretary.*

The Management of Major Amputations was the title of a paper by Dr. J. G. Wyeth. He believed the chief point to be looked after was the prevention of hemorrhage, and next the preservation of as much of the length of a limb as possible. The question of antisepsis and operation during shock was briefly discussed, and two new methods of operation advised. 1. Bloodless amputation of the hip. 2. Bloodless amputation of the shoulder. Diagrams were presented showing the different steps of the operation at the hip. The patient should be placed on the edge of the table, the hip to be operated on well over the corner of the table—Esmarch bandage applied. Then two steel mattress-needles, three-sixteenths of an inch in diameter and a foot long, are inserted, the first one inch and a half below the anterior superior spine of ileum, and slightly to inner side of this prominence, traversing the muscles and deep fascia, passing out posteriorly between the great trochanter and the iliac spine, external to neck of femur.

The second needle is entered below the level of the crotch, internal to the saphenous opening, and passing through the adductors, coming out about an inch and a half in front of tuber ischii. Strong rubber tubing is now wound around the thigh, and above the fixation needles slightly tied. After removing the Esmarch, a circular incision is made, and a cuff, including subcutaneous tissues, down to the deep fascia is dissected off to the level of the lesser trochanter, at which level the muscles are cut and the bone sawn through. All vessels are easily seen and are tied with catgut. The remainder of the femur is then removed by dividing the attached muscles and ligaments in and around the hip-joint.

In some cases it is advisable to do the operation in two sittings.

The same operation was advised for the shoulder-joint. To preserve the length of limb after osteomyelitis, drainage-tubes were used, passed into the medulla after the latter had been thoroughly scraped out with a Volkmann's spoon, and thus a longer stump was secured.

Abdominal Section and Drainage for Purulent Peritonitis was the title of a paper read by Dr. Joseph Price, of Philadelphia. He urged operative interference in all cases as soon as the diagnosis was made.

Surgical Treatment of Biliary Obstruction was read by Dr. H. O. Marcy, of Boston. The article was a very exhaustive one, the literature of the subject thoroughly reviewed, and the various methods of operation discussed. He believed every case of wound or perforation of the gall-bladder should be operated on; also cases of empyema, cystic dilatation, and biliary obstruction that do not yield to medicinal treatment.

Cholecystotomy was indicated in cases where the gall-bladder and the ducts have undergone much pathological changes. When the gall-bladder is resected the entire secreting membrane must be removed.

When a stone is found in the common duct it may sometimes be dislodged by pressure. When this is impossible, crushing may be done. If this fails it should be removed by incision into the duct. He advocated the use of kangaroo tendon for sutures. When the common duct is permanently occluded, from inflammatory or other changes, the cystic duct remaining open and gall-bladder not particularly disorganized or adherent, a permanent fistulous opening may be made. In performing cholecystotomy it is well to remember that gall-bladder walls are very thin, and manipulation must be gentle.

The paper was discussed by Drs. Senn and Deaver.

Gunshot Wound of Brain.—Dr. J. Lee McComas, of Oakland, Md., read a paper on "Gunshot Wound of the Brain—Recovery, with Ball remaining therein." W. C——, male, aged sixteen, shot September 29, 1889; cartridge a 22 short; three grains of powder; weight of ball twenty-eight grains; shape conical. Ball entered a little below the internal end of right arcus superciliaris, passing through the frontal sinus downward and backward to the left as indicated by probe. Considerable hemorrhage. Three hours later was insensible, pupils dilated, vomiting at intervals, blood in right nostril. Temperature, 97 $\frac{2}{5}$° F.; pulse, 52; respirations, 22; pulse irregular, extremities cold. His condition remained critical for many days, but he finally recovered. During this time his symptoms showed that Broca's speech-centre and the island of Reil were injured by the ball, as he had aphasia; and though he understood everything said to him, and made efforts to reply, he could not regulate his speech movements, and was painfully conscious of his defects, as was expressed by crying and becoming angry if questioned or asked to repeat anything. He also had paraphasia, for when he could speak he uttered such words as kame for comb. Nor could he write the alphabet, but always made letter B, and realized his error if attention were called to it.

He has had ptosis, strabismus, and dysphagia in addition,

and just how many of these were due to the bullet, and how many to extravasated blood, cannot be positively said, but probably most were due to the latter cause. He is now well, only more irritable than before injury; works as a painter at great heights, and says he never feels giddy; mouth is slightly drawn to the right, tongue also, eyes act normally, sight is perfect; he can read and write.

FOURTH DAY, FRIDAY, MAY 23D.

Treatment of Flat Foot by Thomas' Method.—This paper, by DR. W. R. TOWNSEND, of New York, was based upon a series of over fifty cases treated by the method during the past two years at the Hospital for Ruptured and Crippled, New York.

The method consisted in building up the inner side of the shoe from extreme back end of heel to a point just behind great toe—the raised portion being from one quarter to one-half inch, varying according to the age of the patient and severity of case. Symptoms of flat foot were briefly given, and the conclusion reached that the method could be used to advantage in cases where the spasm was not a marked symptom. In these cases it gave no relief and could not be tolerated by the patient, as a rule. Its advantages were cheapness, simplicity, and success if used in proper cases. It relieved or improved the symptoms but could not be said to cure the cases, as in none of those so treated was the normal arch ever restored.

DR. BELL, of Indiana, made some remarks upon intubation of the larynx.

The two following papers were read by title: "Fractures of the Base of the Skull," by Dr. H. C. Wyman, of Detroit; "Abscess of the Prostate Gland," by Dr. H. C. Hart, of Philadelphia.

The Section then adjourned, after having passed a vote of thanks to the presiding officer, Dr. Watson, of Jersey City.

SECTION ON PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

THIRD DAY, THURSDAY, MAY 22D.

(Continued from page 627.)

DR. KIERNAN, of Chicago, had seen but one case in which there were the characteristic symptoms of so-called hydrophobia, and this diagnosis was confirmed by a physician who claimed to have seen fifteen cases. The man, however, recovered, and then it was said not to have been hydrophobia. This case led him to doubt the existence of a distinct affection called hydrophobia. Unlike in other infectious diseases, the period of incubation, it was said, might be years; and the type or severity of the disease would vary according to the point of inoculation. Not a single symptom attributed to hydrophobia but could be produced by tansy, alcoholism, fear, and epilepsy. When an epidemic of fear of hydrophobia existed, many cases were reported; at other times there were few. Formerly the annual death-rate from hydrophobia in Paris had been said to be five; after Pasteur's experiments it rose to twenty-one.

Imagination in Pigs.—DR. SCOTT, of Cleveland, thought the development of rabies in pigs, and others of the lower animals, following the bite of the dog suffering from rabies could not be accounted for by fear or the workings of the imagination, and if simple anger on the part of the dog was all that was necessary to cause hydrophobia in his victim, all the pigs in the country would show rabies.

He once attended a boy who had what he believed was hydrophobia, and the medulla oblongata on gross examination was found only of half the usual size, and surrounded by serous exudate. Microscopical examination was not made.

A Case Treated by Pasteur.—DR. L. D. BULKLEY, of New York, put on record, for the first time, the case of a child who, three or four years ago, was bitten on the nose by what was believed to be a rabid dog. The dog bit some other animals, which afterward became mad; but before he could notify the people not to kill the animal this had been done. The body was sent to Liautard, who examined the cord, etc., and expressed the opinion that it was a case of rabies. Inoculations of other animals, caused the disease. About seventeen hours after the bite, too late to be useful, Dr. Bulkley cauterized the child's nose. He accompanied the parents immediately to Paris, and the next day saw Pasteur, who wished to postpone inoculations until he could telegraph Liautard, but at the urgence of Dr. Bulkley made the inoculations at once. The child had shown no symptoms of hydrophobia up to the present—four years.

Hydrophobia Produced by the Polecat.—DR. SEARS said that in Texas children bitten by polecats, or by dogs which had previously been bitten by this animal, had become hydrophobic, and he knew of no remedy. He, therefore, was very thankful for the work being accomplished by Pasteur.

The Experience of an Old Practitioner.—DR. N. S. DAVIS had seen but one case of supposed hydrophobia. It was that of an engineer who had first been seen by other physicians, who sent him to the hospital, where he died within eighteen hours. Neither the patient, while conscious, nor any of his friends, could recall the history of a dog-bite or of any injury. He had been on something of a spree two or three weeks while out of a job.

Dr. Davis had seen many cases of dog-bite, but none in which the animal had not been killed, so that the existence of rabies could not be proven.

Rivals Pasteur's Treatment.—During the past twenty years he had directed such patients to keep the wound covered by a cloth saturated with a solution of carbolic acid and hyposulphite of soda, and to take in water ten grains of the hyposulphite of soda three times a day, continuing it three or four weeks. He did not pretend to say this prevented the development of hydrophobia, but none of his cases had had it, and therefore it could be said he had had better results than Pasteur.

An aged physician from Ohio said he had seen numerous persons bitten by dogs, but had never seen a case of hydrophobia.

Malaria and the Causation of Periodic Fevers.—DR. H. B. BAKER, of Lansing, advanced facts in support of his view of the causation of periodic fevers expressed in a paper two years ago. The facts consisted of charts based on statistics of intermittent fever and the state of the temperature at the time, as observed in Michigan and during the War of the Rebellion ("Medical and Surgical History of the War"). It appeared from these tables that the chief factor in the causation of intermittent fever was changes of temperature; and while he did not deny the existence in the blood of the elements or germs described by Osler and others, he held that these were followers, and not the producers, of the fever.

These changes in temperature were most common in tropical regions, next in the temperate—the difference between the night and day air being often very marked. Here, too, the body was least able to react quickly under such sudden atmospheric changes. Remedies directed against torpidity of the liver and toward increasing bodily vigor were among the most efficacious.

Changes of the Blood in Malarial Fevers.—DR. GEORGE DOCK, of Galveston, presented diagrams and read an exhaustive paper on changes of the blood in malarial fevers. His own studies, including examinations of the blood in thirty patients, were confirmatory of what had been seen by Drs. Sternberg, Osler, Councilman, and others. He had, however, seen no cases of the quartan type. In some of the specimens under the microscope he was able to study the bodies contained in the blood of the malarial patients from the small amœboid stage to the colorless, transparent cells of the corpuscles. They disappear under treatment by quinine or by nitrate of potas-

sium, the former of which was the well-known specific in these affections. The presence of these bodies had enabled him several times to make a differential diagnosis, and settle on a method of treatment. He regarded them as causative.

Dr. Baker, of Lansing, advanced some reasons for the belief that, although such bodies existed in the blood, they were not causative of intermittent fevers.

SECTION ON DISEASES OF CHILDREN.

(Continued from page 630.)

Third Day, Thursday, May 22d.

The Significance of Fever in Children.—Dr. W. L. Stowell, of New York, read a paper on "The Significance of High Temperature in Children." The infant had naturally a higher temperature of from one to two degrees than the adult. He specified as to what was a dangerous temperature in the various infantile maladies. Each disease had its own peculiar thermal features which did not always coincide with those of the same diseases in adults. In many of these clinical conditions the prevalent use of antipyretics was not only useless, but often injurious. Moderate dosage of them relieved symptoms. Aconite and veratrum viride were serviceable if given early. Quinine was useless for reducing temperature, but good in small tonic doses. The tendency of many heat-reducing remedies to produce cardiac depression should not be lost sight of. In febrile processes in children there was a tendency toward reparative processes rather than toward those of a degenerative nature. Feeding was of primary importance. Diet itself might be a febrifuge.

Dr. E. Cutter, of New York, had often reduced fever by a diet of beef without any medicine whatever. He regarded all fever as an effort of nature to get rid of offending material.

Dr. W. P. Watson, of Jersey City, regarded heart failure or nervous symptoms as the indication for vigorous antipyretic measures. Sponging, if properly done, was advisable. Digitalis should be given with antipyrine and kindred remedies. Carbonate of ammonia could also be given, but it should be used in frequent doses. We should not forget that fever often upset the secretions of the stomach; hence the advantage of external over internal antipyretic measures.

Dr. Frank Woodbury, of Philadelphia, thought we had neurotic and poison fevers. The latter called for the removal of the cause, which could be accomplished by internal medication. In the former cooling the surface of the body often alone sufficed. The eyes as well as the head proper should be covered with wet towels, so as to shut out all sources of reflex irritation. Fever was a form of energy. The latter normally was expended in keeping up proper bodily heat and in the performance of automatic and voluntary motor functions. In disease, the first avenue took all the energy. Hence rest and the reduction of the heat-production were the therapeutic indications. Fats applied to the skin in exanthems were often as good as cooling the surface by fluids.

Dr. Work, of Indiana, paid special attention to the emunctories and used tepid (not cold) water, particularly on the back of the head and neck.

Dr. E. F. Brush, of New York, had found that where the mercury rose very rapidly in the thermometer when the latter was placed in position, we usually had a mild case of disease, but when it rose more slowly, even though not as high, it was a more serious matter. Whenever fever rose to 103°, he gave warm water injections, and if bowel action was necessary he gave a small turpentine enema.

Dr. Larabee, of Louisville, said he tried to manage rather than to treat fever: the less medicine used the better. Hyperpyrexia should be treated, but not mere pyrexia. Those cases of high temperature due to neuroses were best treated by the warm pack. He advocated rectal injections with cold water coils for the head. A temperature of 104° F. needed treatment.

Dr. Boyd, of Pennsylvania, had found the best way to reduce temperature in children was to apply tepid water over chest and abdomen.

Discussion on Croup and Diphtheria.—The Section then adjourned to listen to the discussion on Croup and Diphtheria before the Section on Laryngology. This was opened by Dr. Carl Reiter, of Philadelphia, who advocated the duality of the diseases. Dr. William Porter, of St. Louis, believed in their unity, as did also Dr. Jacobson, of Syracuse, N. Y. "Croup" signified to him a laryngeal obstruction due to false membrane. He thought the attempt to differentiate the disease as often attended with great danger to the public health. If a diagnosis of croup was made, isolation was apt to be neglected. The disease was thereby conveyed to others. There was undoubtedly a croupous inflammation of the larynx without any pharyngeal exudate, not contagious and without constitutional symptoms. Cases of this nature which did spread to others could possibly be explained by the fact that a preceding fibrinous pharyngitis had been overlooked.

Dr. C. E. Early read a paper on "Croup," showing that what the early writers described as this disease coincided exactly with what we now call diphtheria. He believed in the unity of the two. He placed reliance in the treatment with ipecac, chlorate of potash, and chlorate of soda in solution. In manifestly diphtheritic cases, he added bicarbonate of soda, cared for the emunctories, and stimulated freely.

Dr. H. H. Didama, of Syracuse, N. Y., was in favor of unity.

Dr. W. H. Daly, of Pittsburg, advocated the use of pure calomel as the best plan of treatment. He had brought forward this idea four years ago. Further experience had only confirmed his earlier views. It should be given in doses of two to five grains every one, two, or three hours, up to free catharsis.

A paper by Dr. F. E. Waxham, of Chicago, was read by the Secretary. He advocated intubation as preferable to tracheotomy. He had had 100 successes in 285 cases, or thirty-five per cent.

The subject was further discussed by Drs. Shimmel, of Philadelphia; Brush, of Mt. Vernon, N. Y.; Scott, of Cleveland, O., and Shirley, of Detroit. Dr. Scott advocated the use of a saturated solution of iodoform in ether. Dr. Brush had found that the best way to feed intubation cases was to have the patient flat on the back and to use a nursing-bottle with a long tube.

Fourth Day, Friday, May 23d.

The following papers were read by title: "Further Observations upon Foot and Mouth Disease in its Relations to Human Scarlatina as a Prophylactic," by Dr. J. W. Stickler, Orange, N. J.; "Notes on a Case of Tetany," by Dr. Jacob Schenck, Mount Carmel, N. Y.; "The Importance of Preliminary Treatment of the Nasal Mucous Membrane before Resorting to Operations," by Dr. Carl Seiler, Philadelphia, Pa.

The following paper from the Section on Dietetics was also read by title: "Diet in Consumption," by Dr. Hubul Judd, of Galesborough, Ill. After a few remarks by the Chairman the Section adjourned.

The concluding work of the series Rougon-Maquart, by Emile Zola, is to be entitled "Docteur Pascal." The author is said to have taken for his hero and model the celebrated chemist and physiologist, Claude Bernard, whose domestic life, it appears, was so unhappy that he described himself as one of the "martyrs of marriage."—*Medical Press.*

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. SANSOM ON RAPID HEART—PERSISTENT THYROID DUCT—MYOMA OF UTERUS BECOMING SARCOMATOUS—TUBERCULAR DISEASE OF THE LIVER WITH CAVITIES—SUCCI'S FAST—SURGEON T. H. PARKE.

London, May 10, 1890.

The Medical Society's annual "Harveian Oration" was delivered on Monday last by Dr. Sansom, Physician to the London Hospital. Dr. Sansom took for his subject the consideration of certain cases of abnormal rapidity of the heart's action. He explained that he did not propose to consider any cases in which valvular or other organic heart disease was found to precede the signs of morbid acceleration. He also excluded cases in which the condition of rapidity was associated with states of disease accepted by general experience as predisposing causes of such acceleration—such, for instance, as fever, the direct influence of certain germs, marked anæmia, hemorrhage, the operation of certain poisons, and conditions of peripheral irritation such as the presence of undigested food in the alimentary canal, and the sometimes pronounced effects of intestinal worms. Dr. Sansom also excluded cases in which the acceleration was solely paroxysmal ("paroxysmal hurry of the heart"), and also cases of palpitation, when such symptoms occurred in the case of a heart manifesting at the times when such palpitation was absent a normal rate of action. Restricting his review of cases to those not excluded for the above reasons, Dr. Sansom employed the term "The Rapid Heart" to designate the clinical condition met with. In some cases there was reason to believe the heart's action was quickened for very protracted periods. The limit of normal frequency was fixed by the orator at 90 in the adult; he thought we must regard as morbid a frequency exceeding this. (In children the cardiac pulsations were normally much more rapid, and were readily excited to a high degree of frequency by various intrinsic and extrinsic causes.) There were several classes of cases in which, in adult life, a long-persistent abnormal rapidity of the heart's action had been observed. In Graves' disease the pulse-rate might be 100 or 150, and under excitement might rise to 180 or 200; this acceleration of the heart's action was often the first sign, and might be for long periods the only manifest sign, of the affection. The disease was serious and often fatal, and the chief cause of danger was in the cardiac involvement; in fatal cases the heart was constantly found dilated and hypertrophied, but in no considerable degree. Another class of cases occurred in soldiers. Dr. J. M. Da Costa applied the term "irritable heart" to designate an affection he observed among the men engaged in the American Civil War. Dr. Da Costa observed more than three hundred cases of persistently quick action of the heart, and many of them manifested no obvious departure from health; the respiration-rate was not quickened *pari passu* with the pulse. "Rapid heart" had also been noticed in association with osteo-arthritis by Dr. Kent Spender, of Bath, who said: "The pulse quickens with the earliest objective signs of osteo-arthritis, there is a gradual rise until the numerical frequency of 110, 115, or 120 is reached, and there is scarcely any physiological variation during day or night. And the cardiac tumult does not always subside, even when the osteo-arthritic phenomena come down; a quickness and irritability continue which no medicine effectually controls." Cases of rapid heart without notable morbid association also occurred and Dr. Sansom proceeded to consider such cases in detail. Dr. Bristowe had published nine cases, and excluding one of these on account of the co-existence of organic (valvular) disease, and another because the symptoms were more strictly paroxysmal, seven cases remained. In several of Dr. Bristowe's cases the patients were unconscious of anything abnormal. Yet five out of the seven cases died with signs which seemed to show that the affection was in causal relation with the deaths. One case ended in albuminuria, and death, after three weeks. In another, after undue rapidity of heart—the rate being from 200 to 260—had continued for six weeks, agonizing pain at the pericardium supervened, and the patient died with symptoms of pulmonary obstruction and failing heart. One of Dr. Bristowe's cases was ushered in by an attack supposed to be a sunstroke. Of six cases mentioned by Dr. Broadbent, one became hemiplegic and another died in convulsions. In one fatal case recorded by Dr. Bristowe, the heart was found post-mortem to be somewhat dilated and hypertrophied, but both the valves and the walls were healthy. In a case noted by Drs. Dreschfeld and Maguire, in which there was a history both of syphilis and of alcoholic excess, the heart was large and its tissue degenerated. The question arose whether the affection was one of the myocardium or of some portion or portions of the nervous system. Dr. Bristowe thought it had no special connection with cardiac disease, and that dilatation and hypertrophy of the heart, when occurring independently of valvular mischief, were the slowly-developed consequences and not the causes of the disturbance. On the other hand, Dr. Samuel West regarded cases of paroxysmal hurry of the heart as due to an organic lesion of the muscular substance, which might be in some cases a form of chronic interstitial myocarditis, consequent, perhaps, on rheumatic pericarditis or on syphilis, and thus related to fibroid disease of the myocardium.

Dr. Sansom then gave a summary of his own experience on the subject. He had notes of seventy-five cases, which had been under his own observation. He did not include in this series any in which, anteriorly to the signs observed, there had been any evidence of organic cardiac disease, nor any with which any other structural disease was cognately in association, nor any manifesting a palpitation which was only paroxysmal; but only those cases in which there was observed an abnormally rapid action of the heart for comparatively protracted periods. He grouped the cases in two divisions: First, those in which there was no association whatever with the recognized signs of cardio-vaso-motor disease, 46 in number, comprising 30 females and 16 males; secondly, cases in which this association existed, 29 in number, 24 females and 5 males. In many of the cases in the first group the onset was ascribed to physical or mental overstrain (shock), but in others the onset of the symptoms was gradual, and associated only with vague dyspepsia; restlessness and insomnia were common. The conditions in the two sets of cases were closely allied, both being probably secondary to nervous implication. The differences between the two sets of cases were of extent rather than of kind. In the very marked cases treatment was practically useless, but it had proved of value in the less severe ones. He recommended particularly the application of a continuous current of electricity over the great nerve-centres. One of his cases received marked benefit from the application (continued daily for ten days) of weak galvanic currents from the cervical spine to the region of the great nerves in the neck.

Some interesting subjects were brought forward at the last meeting of the Pathological Society. Two cases of persistent thyroid duct were described by Mr. Raymond Johnson. Mr. Albau Doran exhibited a myomatous tumor of the uterus, which was becoming sarcomatous, and had been removed from a woman thirty-one years of age, by Mr. Thornton. Among the other specimens shown was one of tubercular disease of the liver. This was exhibited by Doctor Hector Cameron. The tubercular disease was very extensive, and there were numerous cavities in the liver containing caseous material. The case was not one of actinomycosis, for the ray fungus had been sought for and could not be found. The patient had been admitted into hospital for thoracic symptoms,

and after death tubercular disease was found in both lungs.

Succi's fast of forty days continues to excite interest both in professional and lay circles. Though not the first experiment of its kind, it is perhaps the most carefully conducted one which has hitherto taken place in this country, and the surrounding conditions were such as to throw no doubts on the genuineness of the fast. The most regrettable feature of the affair is the sensationalism which has been imported into it. This element still continues. While during the fast advertisements of "Succi's fast" were to be seen on every hand, we are now similarly inundated with advertisements headed "Succi's feast," and puffing the various foods he is taking to recuperate with.

The gold medal of the British Medical Association is to be presented to Surgeon T. H. Parke, of the Army Medical Department, late surgeon to Stanley's expedition.

OUR PARIS LETTER.

(From our Special Correspondent.)

ACCIDENTS WITH COCAINE—ANTIDOTES—NITRITE OF AMYL AND ETHER—NAPHTHOL IN PURULENT OPHTHALMIA—PROS AND CONS OF CURETTAGE—GENERAL TREATMENT OVERLOOKED!—THE MICROBE OF OLD AGE AN HEREDITARY PRODUCT.

PARIS, May 2, 1890.

DR. DELBOSC, a pupil of Dr. Reclus, Hospital Surgeon, who vaunts the employment of cocaine in surgical operations, has just published a statistical and clinical report on the accidents produced by this substance. He collected the histories published of accidents, from which he has been able to establish that up to the present time, only five deaths have occurred after the use of cocaine. This proportion would evidently go against the method if only the bare facts be accepted without interpreting them. From the various observations published, it would appear that death resulted from the enormous doses that were administered, varying from 75 ctgr. to double that quantity. According to Dr. Delbosc cocaine may be employed at the maximum dose of 20 ctgr., although he would not advise such a dose ordinarily, as beyond that quantity serious accidents occur. The first death however, from cocaine took place after a dose of only 75 ctgr. The penetration of the liquid into a vein has sometimes been noticed, and it is probable that this may thus explain the production of accidents with a feeble dose. To obviate this accident it is sufficient to push the piston of the syringe according as the needle is forced into the tissues. It is possible that a vein may be pricked and a drop of the liquid be introduced into the calibre of this vein, but the rest of the solution will certainly be diverted into the cellular tissue. Moreover, to avoid the rapidity of absorption, solutions too concentrated should never be employed. Dr. Reclus has adopted a two per cent. solution and he has never since had any accident, although he has performed, since June last, twenty-five important operations, among which are cited castrations, radical operations for hydrocele and hernia, and two gastrotomies. Dr. Reclus observes that it is not necessary in order to obtain anæsthesia to push the needle into the muscles or the subcutaneous cellular tissue, but into the thickness of the dermis. In order to combat the accidents which, in spite of all precautions, may occur, the nitrite of amyl, injections of ether, and caffeine are indicated. Against convulsive accidents chloral or chloroform may be employed.

In cases of purulent ophthalmia, Dr. Budin, Accoucheur at La Charité Hospital, gives the preference to the use of naphthol for the following reasons: With naphthol the swelling of the lids yields rapidly, the cauterizations will be less frequently required, and if the naphthol will not altogether replace the nitrate of silver, it renders great service as an adjuvant. In the treatment of purulent ophthalmia it is far preferable to boric water. Dr. Budin, in his clinical observations, cites a case in which, the solution of boric acid not having produced any amelioration, with the naphthol the conjunctivitis, which lasted a long time, rapidly disappeared. Since the researches of Dr. Budin, naphthol A, which is twice as antiseptic as naphthol B, has been adopted in practice. Dr. Valude and, in a recent thesis, Dr. Dupont cite observations in which the naphthol A gave excellent results. The non-alcoholic solution employed, which is more difficult to obtain, is composed as follows: Naphthol A, 20 ctgr.; distilled water, 1,000 gm.

A debate has been going on for some time at the Société de Chirurgie on the pros and cons of "curettage" and cauterizations in the treatment of endometritis, but no practical conclusion has been arrived at. Among the advocates for curettage may be named, Dr. Bouilly, who considers that curettage applied to the uterine cavity is the best remedy for endometritis. Dr. Trélat, whose death was reported in my last, stated at the meeting of the Société de Chirurgie, just before his fatal illness, that he preferred curettage for the cure of the different forms of metritis, on the grounds that the sticks of the chloride of zinc were inefficacious, because they acted only on the neck, which is the narrowest part, and not on the uterine cavity, which, being larger, is not in contact with the caustic, and he had seen several women who became affected with stenosis of the uterine neck after this treatment. Dr. Polaillon, who is a great partisan of intra-uterine cauterization, observed that while curettage may have cured metritis when practised by able hands, it also has a tendency to produce stenosis of the uterine neck, but he thought that in either case, if proper measures be taken, this accident might be prevented. Dr. Reynier, who had practised both methods, stated that with curettage in the treatment of endometritis he had obtained immediate amelioration, but at the end of five or six months, the symptoms often reappeared. Of fifteen operations of this kind, he obtained only five perfect cures. He then tried the treatment by the sticks of the chloride of zinc, and had seen hemorrhages cease immediately, but to reappear later on, notwithstanding that the patients were confined to their beds until after the return of the menstrual period, that is to say, during thirty-five or forty days. Of six patients that came under his notice, three had atresia of the uterine neck. This atresia may be produced rapidly, but more frequently it takes place slowly. He has therefore returned to curettage followed by cauterization with the chloride of zinc or with creasote. The author thinks that curettage prepares the way for cauterization which it renders more efficacious. Cauterization with the sticks of the chloride of zinc may appear to be an operation more simple than curettage, but it is not applicable to all cases, although it succeeds perfectly in old cases of chronic metritis, and particularly in women approaching the age of the menopause. Another group of surgeons, among whom may be named Drs. Richelot, Lucas-Championnière, and Terrillon, will have neither curettage nor cauterization in the treatment of these cases, as they consider them a waste of time, but at once resort to the more radical measures such as laparotomy, hysterectomy, etc. It may be remarked that during the long discussion that has taken place with reference to uterine maladies and their treatment, no allusion whatever has been made to the general treatment of the patients, the speakers seeming to forget the intimate connection that exists between the uterus and the other parts of the organism. However brilliant surgical operations may be, they are still incomplete without general treatment.

"Professor Brown-Séquard distanced." Under this heading Dr. Burggraeve writes in his *Répertoire Universal de Médecine Dosimétrique* that a Dr. Malin-Conico, of Naples, pretends to have discovered the microbe of old age. The publications of that country announce very seriously that the microbe of old age exists and is trans-

mitted by heredity; invades with age the entire human organism, which it ravages and destroys, leading to caducity and finally to death. The above-named Dr. Malin-Conico hopes thus to have found the means of combating this invisible enemy, and thus preventing man from getting old.

At a recent meeting of the Academy of Sciences, Professor Verneuil exhibited divers plastic models of deformities of the feet. These deformities, according to the author, are analogous in appearance to club-foot coming on after phlebitis, but very rarely, as out of fifty cases he had observed only three for the first time. The muscles in the interior, that is those nearest the bone, are affected in these curious deformities, which distinguishes them from club-foot, in which, on the contrary, the muscles of the exterior are affected.

The Paris Academy of Medicine has opened to competition a prize of the value of one thousand francs for the best work on the hygiene of infants. The following is the question proposed: To determine what are, in the artificial feeding of infants, the value and the effects of raw milk, warmed, or boiled milk, respectively. The papers, which should be written in French, the other academical rules being observed, are to be forwarded to the Academy before March 1, 1891.

ACTUAL WORK REPRESENTED BY A SPARK OF STATIC ELECTRICITY.

To the Editor of the Medical Record.

Sir: In my article upon "The Place of Static, or Frictional Electricity in Medicine," published in your issue of May 31st last, I made a calculation, based upon actual tests, that a single ordinary static spark represented a muscular energy expended equivalent to raising 1 pound 1 foot per second. That is to say, the energy in a spark translated into muscular work equals the unit of work termed a foot-pound. This, so far, was correct, and served to demonstrate what had been denied, that frictional electricity penetrates the skin and affects deeper tissues.

But in the subsequent conversion of this estimate into horse-power, in order to make the illustration more forcible, an error crept in greatly to the disadvantage of the spark-power. The spark energy is equal to half-horse power per *minute*, not per hour, as printed, and the words in the article relating to this point should read.

"The muscle therefore raises 5 pounds per second, and to raise 550 pounds (the unit of horse-power) will require 110 seconds, or about 2 minutes. The actual work, therefore, capable of being accomplished by the muscle under the stimulus of the spark is at the rate of 1 horse-power every two minutes, or ½ a horse-power per minute."

I am, very truly yours,

William James Morton, M.D.

36 West Fifty-Sixth Street, New York, June 3, 1890.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 18 to May 31, 1890.

By direction of the Secretary of War, a board of Medical Officers to consist of Lieutenant-Colonel Anthony Heger, Surgeon; Major John Brooke, Surgeon; Major Robert H. White, Surgeon; will assemble at the United States Military Academy, West Point, N. Y., June 7, 1890, to examine into the physical qualifications of the candidates for admission to the Academy and, in connection with the Superintendent of the Academy and Commandant of Cadets, the members of the graduating class. Reports of the proceedings of the board will be forwarded through the Superintendent of the Academy, to the Adjutant-General of the Army. Special reports will be made in the cases of any graduates deemed to be physically unfit for the military service, and also in the cases of candidates who may be admitted on probation or rejected. S. O. 121, par. 3, A. G. O., Washington, D. C., May 23, 1890.

Girard, J. B., Major and Surgeon. Granted leave of absence for one month, to take effect as soon after June 1st proximo as a medical officer can be sent to Fort Lowell for temporary duty. S. O. 48, par. 1, Headquarters Department of Arizona, May 17, 1890.

DeWitt, Theodore F., First Lieutenant and Assistant Surgeon. Relieved from duty at Willet's Point, N. Y., and will report in person to the commanding officer, Fort Ringgold, Tex., for duty at that station, relieving Captain Carter. S. O. 119, par. 2, A. G. O., May 21, 1890.

Carter, W. Fitzhugh, Captain and Assistant Surgeon. Upon being relieved will proceed to West Point, N. Y., and report in person to the Superintendent of the United States Military Academy, for duty at that station. S. O. 119, par. 2, A. G. O., May 21, 1890.

Benham, Robert B., Captain and Assistant Surgeon. Relieved from further duty at Madison Barracks, N. Y., and will report in person to the commanding officer Fort Wadsworth, N. Y., for duty at that station, relieving Captain Winne. S. O. 119, par. 2, A. G. O., May 21, 1890.

Winne, Charles K., Captain and Assistant Surgeon. Upon being relieved will proceed to Fort Snelling, Minn., and report in person to the commanding officer thereof, for duty at that post. S. O. 119, par. 2. A. G. O., May 21, 1890.

Alden, Charles H., Lieutenant-Colonel and Surgeon, and Billings, John S., Major and Surgeon. By direction of the Secretary of War, the above-named officers of the Medical Department will proceed to Berlin, Germany, as delegates to the International Medical Congress which is to meet in that city in August next. After the adjournment of the congress the officers named will return to the United States and rejoin their proper stations. S. O. 116, par. 11, Headquarters of the Army, A. G. O., Washington, D. C., May 17, 1890.

Billings, John S., Major and Surgeon. Will while abroad under his orders to attend the International Medical Congress at Berlin, Germany, and before returning to the United States, visit, on official business, such points in Great Britain, France, Italy, Germany, Belgium, Holland, and elsewhere, as may be deemed necessary by the Surgeon-General of the Army, and under such special instructions as he may receive from the Surgeon-General. S. O. 116, par. 12, Headquarters of the Army, A. G. O., Washington, D. C., May 17, 1890.

Loring, Leonard Y., Major and Surgeon, now on sick leave of absence until further orders. By direction of the Secretary of War, relieved from duty in the Department of Arizona. Par. 14, S. O. 115, A. G. O., May 16, 1890.

Wood, Leonard, First Lieutenant and Assistant Surgeon. Having completed at New York City the duties assigned him in S. O. 29, April 30th, Division of the Pacific, to return to his station in that division. Par. 19, S. O. 115, A. G. O., May 10, 1890. Granted leave of absence for one month. Par. 20, S. O. 115, A. G. O., May 16, 1890.

Benham, Robert B., Captain and Assistant Surgeon. By direction of the Secretary of War, so much of paragraph 2, S. O. 119, A. G. O., May 21, 1890, from this office, as relates to him is amended to read as follows: Captain Robert B. Benham, assistant surgeon, will proceed from Madison Barracks, N. Y., to Fort Wadsworth, New York, and report in person to the commanding officer of that post for temporary duty.

Heizmann, Charles L., Major and Surgeon. Leave of absence granted for one month. S. O. 39, par. 1. Department of Texas, May 19, 1890.

THE ORIGIN OF SPUTA IN SUBACUTE COUGH.[1]

By W. PEYRE PORCHER, M.D.,

FORMERLY LECTURER ON DISEASES OF THE THROAT AND NOSE IN THE MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA, AND ON MATERIA MEDICA AND THERAPEUTICS AND DISEASES OF THE THROAT AND NOSE IN THE CHARLESTON MEDICAL SCHOOL.

Having had occasion to write a brief article on this subject some months ago, and having had many opportunities for testing the value of the methods employed, I have thought it worthy of being brought before you with some elaborations as follows:

The following notes of cases will illustrate forcibly the conclusion that has urged itself upon me with regard to the origin of sputa in most cases of subacute cough. I do not wish to be understood as implying that all sputa has its origin in the nose and naso-pharynx, any more than I wish to be understood as asserting that the remedy which proved sufficient for the cases cited will act as a panacea for all coughs. But I do wish to say — in the great majority of cases of subacute cough, resulting, as they do ordinarily, from one or more attacks of rhinitis, and even when the cough has existed for a length of time—that treatment directed to the nose and naso-pharynx alone will stop these attacks, as well as many other affections of the upper air-passages, without any applications being made to the larynx or any medicine being given internally.

The first case was that of a patient who, having undergone a fatiguing journey, took a severe cold, which was followed by a violent cough, accompanied with the usual ejectment of sputa in large quantities. A single application of a solution of nitrate of silver (grs. lx. to ℥ j.) to the naso-pharynx was sufficient to materially lessen the cough and cause a decided diminution of the sputa.

A continuance of the treatment relieved him entirely of the cough without a single application having been made to the larynx or trachea, or any medicine given internally. The patient, having been under the impression that the lungs and bronchi were the source of the discharge, expressed himself as being "bewildered" at its sudden disappearance, as well as at the cessation of his cough and asthma, and said that he could not have believed it possible had not it occurred upon his own person.

The next case was very similar to the first, except that it was more of a chronic character.

The patient had previously had several attacks of cough of more or less severity; had gotten thin and pale, and thought himself destined to become a consumptive from the amount of sputa brought up as well as from the obstinacy of the attacks. His septum nasi was deflected to such an extent as to practically occlude his left nostril, and he was therefore dependent upon the right for breathing.

His treatment consisted strictly of applications of nitrate of silver to the naso-pharynx (℥ j. to ℥ j.) every two days until the cough disappeared.

It was especially striking in this case how suddenly the cough and sputa were checked. The attack was at its height on his first visit to me, and that night he had very little cough or sputa. This was due alone to the local treatment, and the large quantity of sputa which he had been spitting up for days past could only have come from the naso-pharyngeal space.

Now, if, as ordinarily stated, most if not all of the sputa brought up by cases of subacute or even chronic cough comes from the larynx and bronchi, how is it possible for a single application of any medicament or any succession of such applications to check the formation of a bowl of sputa in a single night? And yet I am prepared to assert that such has been my experience, and that a continuance of the treatment, in many cases, will cause a complete cessation of the cough and sputa.

It might be said here that this is merely the doctrine warmly advocated by Dr. Horace Green so long back as 1849, but I will state that this is an error, as proved by the following extract from his brochure on "Observations on the Pathology of Croup, with Remarks on the Treatment by Topical Medications:"

"A solution of nitrate of silver (grs. xl. to ℥ j.) was applied as follows: The head of the child, thrown back, was firmly held by an assistant, the tongue depressed, and a small round sponge, fastened to a bent probang of whalebone and dipped in the solution, was passed over the top of the epiglottis and pressed suddenly downward and forward into the cavity of the larynx."

As seen, the applications were made entirely to the larynx, and not to the naso-pharynx as in my cases. Although Dr. Green reiterates the statement that "the exudative inflammation of croup invariably commences in the superior portion of the respiratory passages and invariably passes downward and never in the opposite direction," I would add here that I do not by any means always confine myself to this one agent, as did Dr. Green, but I believe that, after the nose and naso-pharynx have been thoroughly cleansed of the thick viscid secretions, by means of antiseptic lotions, peroxide of hydrogen, listerine, etc., and all pathological incongruities, as deflections, ecchondromata, etc., have been removed from the nostrils, that many other astringents would prove of service, notably iodine, chloride of zinc, etc.

For additional proof I would say that the universal history of the majority of phthisical cases (excepting, of course, such as distinctly originate in the lung, as from various forms of pneumonia or true inflammations of that organ) is that there was first a severe cold, or a succession of colds, beginning in the nose and followed by a cough, and when that became sufficiently chronic the case would immediately be pronounced phthisical by the casual observer. The presence of chronic pharyngitis and rhinitis would certainly be detected in such cases, and proper treatment directed to those parts in the early stages will certainly check the progress of the disease, even in some cases where the cough has existed so long that disintegration of lung-tissues or cavity formation has begun.

Cases of this kind can easily be multiplied, but these suffice to indicate the source of the discharge as well as prove the beneficial results of the treatment.

Lenox Browne, in his last work on "Diseases of the Nose and Throat," makes the statement that it is the universal rule for inflammation in the upper air-passages to pass downward, and a rare exception for it to come from below upward; and nowhere is this rule more forcibly illustrated than in the invariable habit of patients to attribute the origin of an inflammation in the larynx to a previous rhinitis.

The most natural corollary to this is that in inflamma-

[1] Read before the South Carolina Medical Association, April 23, 1890.

tions of the larynx the nose and naso-pharynx are the principal sites to which treatment should be directed, and the deduction would be that the inflammation above produced the sputa, and the sputa which descended produced the cough.

The well-known fact that almost all sensations in the throat are referred to the anterior part of the regio laryngo-trachealis will account for the profound impression of patients that the secretion of sputum is entirely produced by the mucous membrane of the lungs and bronchi, whereas experience has taught us that most generally the pathological disturbances are situated in the choana or naso-pharynx, and the proofs of this are:

1st. Physiological: By irritating the parts, as in a case where an application of the galvano-cautery was made to the pharyngeal tonsil the patient asserted that, for the first time, the seat of the pain had been reached—which she had previously located behind the clavicle.

2d. Pathological: By the different causes which give rise to the cough, viz., colds and inflammations of the naso-pharynx, which, in my opinion, rarely, if ever, originate in the larynx.

3d. By the results of local treatment to parts.

Hence we may conclude from this (and opinion generally supports us in the conclusion) that when a patient applies to us suffering from a cough, we need not administer the invariable cough mixtures containing nauseating doses of antimony, squills, ipecac, etc., but simply confine our treatment to the nose and naso-pharynx.

4 George Street, Charleston, S. C.

THE ADVISABILITY OF WIRING RECENT SIMPLE FRACTURES OF THE PATELLA.

By WILLIAM F. FLUHRER, M.D.,

VISITING SURGEON TO BELLEVUE AND MOUNT SINAI HOSPITALS.

(Continued from page 654.)

Case X.—Simple transverse fracture of the left patella from direct violence; wired six days after receipt of injury; drainage-tube removed eight days after operation. Primary union of wound with apparently bony union of patella fragments. Recovery of motion through forty-five degrees at end of ten weeks.

Refracture, which was compound, ten weeks after wiring, through sudden undue flexion of the limb; re-wiring within eighteen hours after the accident, under continuous irrigation with 1 to 4,000 solution of bichloride of mercury. Adhesions in the joint; drainage-tube removed four days later; primary union of the wound; bony union of the fragments with ultimate recovery.

R. H——, truck driver, aged thirty-five, was admitted into Bellevue Hospital September 5, 1887. The patient is of healthy constitution, but is addicted to the intemperate use of alcohol. The day before admission, while working, he was pushed down by a horse and struck his knee upon the board floor. He was unable to rise. Upon admission he was found to have a simple transverse fracture of the left patella near its middle, with one inch separation of the fragments. A posterior splint was applied to the limb and an ice-cap to the knee.

September 11th.—Opium-wash was substituted for the ice-cap as an application to the knee.

Operation, September 14th.—The wiring of the fragments was performed in the usual manner under continuous irrigation with a 1 to 4,000 solution of the bichloride of mercury. The rent in the capsule was two and one half inches long. There was some infolding of tissue over the fractured surface of the lower fragment. The fractured surface of the upper fragment was completely covered with the turned-in tissue, which dipped down as far as the cartilaginous edge of the fragment. This was the largest curtain of infolded tissue that I had ever observed. It was peeled from the broken surface of the fragment but not cut away. One wire was used to hold the fragments together. This was passed fully three-fourths of an inch from the edges of the fragments superficially, and emerged just back of the edge of the cartilage upon the lower surface, a good bite of bone was thus held in its grasp. The capsular structures were sewn with a continuous catgut suture; the skin wound with interrupted sutures of coarse silk. A drainage-tube was inserted at the place of election and a small piece in a gap in the soft parts at the summit of the joint. The limb was then dressed in the usual manner. The patient required about two pounds of ether during the operation.

September 15th.—The patient rallied well from the ether. He complains of no pain.

September 19th.—The wound was dressed under irrigation. There is apparently union by first intention. The tubes were removed. The limb was redressed as before.

September 29th.—The wound was dressed, and found united by first intention.

October 5th.—The granulating spot at site of drainage-tube was touched with a stick of nitrate of silver. Passive motion was commenced, and the limb was protected from injury by a posterior splint.

October 10th.—Limb flexed through ten degrees.

October 23d.—Through a misunderstanding the limb has been almost constantly bandaged to a posterior splint, the knee-joint being left exposed. There is considerable œdema about the joint, and atrophy of the muscles of the thigh. The movements at the joint had been restricted to very gentle and limited passive motion. The splint was removed by Dr. Fluhrer, and the patient was ordered out of bed, directed to exercise the joint more freely, and massage the limb every day.

November 15th.—The patient walks about the yard with a cane. No independent motion between the fragments.

Refracture.—November 24th, the patient bends the leg past an angle of forty-five degrees. He was allowed to leave the hospital on pass. While intoxicated he flexed the leg unduly and refractured the wired patella. He felt the bone snap and then the blood trickle down his leg. He did not fall after the mishap, but walked about one hundred feet upon the sidewalk and then up a flight of stairs. He was immediately brought to the hospital. Upon admission the temporary antiseptic dressings applied by the ambulance surgeon were removed. There was little swelling of the joint. The patella was found refractured apparently in the line of first breakage. The cavity of the joint was opened by a rent commencing at the middle of the cicatrix of the transverse incision and extending outward one inch. The hemorrhage, which was considerable and had soaked the dressings, was easily controlled by pressure. The end of the wire was easily felt in the interval between the fragments. The wound was dressed antiseptically and the limb immobilized upon a posterior splint.

Operation.—November 25th, ten weeks after the first operation and eighteen hours after refracture. This operation was conducted in the same manner as after the first fracture. The transverse incision opening the joint was made directly through the scar of the first operation. A large clot of blood was found between the fragments. The patella had evidently broken in the line of union, which had been bony, as was clearly shown by the rough fractured surfaces. The wire had untwisted and its lower portion was drawn through the lower fragment. It was bent and rested in the interval between the fragments. By means of heavy pliers the wire was withdrawn from the upper fragment. The interior of the joint was very vascular, and the broken patella surfaces bled freely. The cavity of the joint, especially that portion of the synovial pouch extending beneath the upper fragment, was in great measure obliterated by adhesions. A firm band of adhesion reached from the whole extent of the lower cartilaginous edge of the lower fragment to the synovial membrane covering the anterior face of the femur. The large probe could be introduced behind this partition through

a small opening at the outer side of the joint into a small pocket; through this pocket a drainage-tube was passed, emerging at the scar marking its site at the former operation. There was no fibrous tissue infolded upon the broken surfaces of the fragment. A single heavy wire brought them into exact apposition. The wound was closed and dressed in the usual manner.

November 29th.—The wound was dressed and the drainage-tube removed. There was considerable quantity of sero-sanguinolent discharge upon the dressings.

December 8th.—Dressings removed. There is perfect union in the wound. The interrupted stitches were removed. A posterior splint was applied.

December 12th.—All dressings were removed.

December 15th.—The patient is walking about the ward with crutches. He has flexion at the knee to twenty degrees. His thigh is massaged daily.

January 7, 1888.—The patient is fearful of breaking the patella again, and has therefore not exercised the joint as much as he should have done. He has discarded crutches and walks with one cane. There is slight pain and swelling in the joint at night which disappears with a night's rest.

January 26th.—He has been a little braver in moving the joint, and can flex the leg to an angle of forty-five degrees with the thigh. He walks without a stick.

February 7, 1890.—In November, 1888, when he went to work there was flexion just short of a right angle. He has remained at work since that time, it being the same occupation, that of a truckman, in which he was engaged before he broke his patella. He works frequently fifteen hours a day, and handles heavy packages, sometimes weighing eight hundred pounds. He has perfect power of extension and flexion past a right angle. The joint meeting all the demands put upon it in his daily work, he has, as he acknowledges, failed to practise the motions necessary to acquire complete flexion. The thighs are of the same size. The scar is perfectly movable, and lateral motion of the patella is almost as free as on the other side. The joint never swells nor shows any weakness, and the imbedded wire cannot be felt.

Remark.—The compound character of the refracture is not a peculiarity of the open method of suture, for it sometimes occurs after the non-operative method; but that there is a greater liability after the operative procedure is easily understood when we consider that the weakened plane in the soft parts due to the scar corresponds with the plane of breakage in the patella.

Further, this case emphasizes the force of the remarks made upon the preceding one.

Case XI.—Simple fracture of one of the fragments after an old break of the patella; wiring eleven days after the fracture under irrigation with a 1 to 4,000 bichloride of mercury solution; no infolding of fibrous tissue; a strong membrane between the lower margins of the fragments shutting off the joint; bony union without suppuration; at the end of three months recovery of the same imperfect degree of function that existed before the accident. Refracture of the wired fragment nearly four months after the operation; slight separation of the fragments; treatment upon a posterior splint with good union of the fragments; the displaced but unbroken wire causes some annoyance.

O. V——, engineer, forty-eight years of age, was admitted into Mount Sinai Hospital, June 15, 1886. The patient has always been a healthy man. A number of years ago he had a Pott's fracture of the right fibula which has left some deformity and weakness of the limb. About two years ago, while leaning upon his cane, he slipped and fell, striking the left patella against a rather sharp piece of iron machinery, causing a transverse fracture of the patella above its middle. The limb was placed upon a posterior splint and the fragments were held together with adhesive plaster. After confinement to bed for three months there was found three-fourths of an inch separation of the fragments. He then got about upon crutches. At the end of two weeks, in sitting down he bent his knee rather suddenly, heard a snap and felt a sharp pain, especially in the posterior part of the joint, and found that the patella fragments had been further separated. There was not so much swelling or ecchymosis as after the first accident. The leg was placed upon a Hodgen's splint, the fragments being held in position by means of a padded iron ring retained by a rubber bandage. The apparatus was upon the limb for twelve weeks, the patient being confined to bed for fourteen weeks. At the end of this treatment there was one inch separation of the fragments. After this second accident he used crutches for six months and then a couple of canes. In climbing stairs he required help. Since that time locomotion has been difficult. He has not been able to flex the leg beyond an angle of forty-five degrees. The fragments have become gradually separated from a distance of one inch to that of two and a half inches. They can readily be brought to within one inch of each other.

Four days ago the patient, in stepping from the sidewalk, gave his crippled leg a twist. Having his canes as supports he did not fall. He felt a sharp pain in the joint, which soon became much swollen and discolored; the swelling and discoloration were situated lower down the limb than in the previous accidents.

Upon admission to the hospital there was found considerable swelling and ecchymosis about the knee. The two fragments into which the patella was first broken can be readily felt. The smaller and upper fragment is separated from the lower one two and a half inches. The lower fragment is found to be fractured transversely and the pieces of bone when rubbed together produce crepitus. The limb was placed upon a posterior splint and a poultice applied to the knee. The urine is normal.

Operation, June 22, 1886, under continuous irrigation with 1 to 4,000 bichloride of mercury solution.—A good deal of ether was required to anæsthetize the patient. A transverse incision was made over the site of the last fracture. Quite an amount of clotted blood was found in front of and between the fragments, but there was no infolded fibrous structure upon their fractured surfaces. A firm membranous structure was found extending between the cartilaginous surfaces of the fragments, completely shutting off the synovial cavity of the joint. This membrane was dark and rough and of considerable firmness, oozing blood but not breaking when wiped by the sponge. The fragments were drilled in the usual manner. As considerable force was required to maintain them in apposition, the intention of using a disinfected silk suture was abandoned and a single wire suture employed instead. The line of apposition was perfect except at the inner angle, where there was a slight defect due to a secondary fracture of a small piece from the lower portion of the upper fragment. The capsular structures were brought together with a continuous catgut suture—and the skin incision by interrupted sutures of silk. A piece of small-sized drainage-tube was inserted in each dependent angle of the wound. During the operation the cavity of the joint was not seen; no ligatures were used. The wound was dressed antiseptically in the usual manner.

June 23, 1886.—The patient complains of occasional pain in the knee, which disappeared when the padding of the posterior splint was readjusted.

June 27th.—The wound was dressed under irrigation with 1 to 2,000 bichloride of mercury solution. The gauze was saturated with sanguinolent discharge. The tubes were removed. There is apparently primary union. The wound was dressed as before.

July 4th.—The wound was dressed. There was scarcely any discharge upon the gauze. The wound has entirely and soundly healed. A light antiseptic gauze dressing was applied.

July 9th.—The silk sutures were removed. The limb was bandaged to a posterior splint and the patient was

allowed to get out of bed. The highest temperature was 101.6° F. the day after the operation; after that, the temperature was normal.

For some time efforts were made by means of different devices to bring the two principal fragments of the patella in such close apposition that they could be united by operation and suture, but under prolonged extension upon the upper fragment it could be brought only to within about one inch of the lower one, and the attempt was abandoned. On September 22d, at the end of three months from the date of operation of wiring the broken lower fragment, the patient can flex the leg to an angle of forty-five degrees with the thigh. He can extend the leg horizontally to within fifteen degrees of the line of the thigh. The wired fragments appear to be firmly united by bone. He has as much function in the limb as before the last accident. He is obliged to use a cane.

On October 18th, nearly four months after the operation of wiring, while in a distant city, the patient was assaulted upon the street. He was struck upon the back of the head, and in his effort to keep from falling the muscular strain refractured the patella in the line of the last break. He walked to his hotel. On the 20th he was removed to a hospital. The fragments were separated only about one-sixteenth of an inch and easily yielded crepitus.

The wire had not parted. The slight separation of the fragments was probably due to the limited range of flexion and to the lengthened insertion of the extensor tendon the result of the stretched ligamentous union between the two principal fragments. When the leg was carried to the limit of its range of flexion, the gap between the recently broken fragments was increased only one-sixteenth of an inch. There was much less swelling and ecchymosis of the joint than after the occurrence of the last fracture. Fomentations were applied to the joint for a week, at the end of which time the limb was placed upon a posterior splint and the fragments were held in place with adhesive plaster.

December 6, 1886.—I visited the patient, and through the kindness of his attending physicians, was permitted to examine the condition of his limb. There was no swelling of the joint. The line of fracture was to all appearance the same as that before wiring. There was a slight displacement of the fragments. With a considerable amount of force there was apparently a slight independent motion between them. The wire had apparently, without untwisting, cut partly through the bone, and could be felt prominent beneath the skin. In the line of fracture the fragment was notched on the inner edge and slightly grooved upon the outer edge. There was every prospect that there would be either a very short ligamentous union or more probably a bony union.

January 16, 1887.—The patient wrote me that he had acquired some degree of flexion of the leg, but that upon motion there is a pain in the patella that he never felt before, which he attributes to the presence of the wire.

Remark.—This case is one of the illustrations of the accidents that follow imperfect results of non operative treatment, and the disadvantages under which the patient is placed for successful treatment of a refracture.

The influence of the infolded fibrous tissue upon bony union is further shown by the following case, in which the præpatellar structures were untorn.

Case XII.—Simple fracture from direct violence; tapping of the joint; fragments not perceptibly separated; exploration with a needle; bony union without any special apparatus to hold the fragments together; recovery of power of complete extension; flexion to nearly a right angle.

H. S——, aged forty-four, piano maker, was admitted into Mount Sinai Hospital, March 26, 1886. On March 13th, while alighting from a horse-car, he fell, striking upon his right knee. He did not feel anything give way in the joint at the time, but could not get up on account of the pain, nor could he extend his leg or walk. The knee at once became very much swollen, but not very tender. At home ice, and later hot poultices were applied to the knee. Upon examination at home by his attending physician and my house surgeon, crepitus was obtained, and a transverse fracture of the patella was diagnosed. Later the distention of the joint was so great that the fragments could not be readily felt.

On admission the knee-joint was very much distended. The skin over it is reddened, and the joint is very tender. The limb was placed upon a posterior splint, and iced lead and opium wash was applied to the knee.

March 29th.—The knee remains very much swollen. The patella can be felt. There is apparently, upon gentle manipulation, no motion between the fragments. It was also noticed that the liquid in the joint lifted the patella as a whole, and that fluctuation was in the surrounding sac and could not be felt through any interval between the fragments. Under elastic compression and with antiseptic precautions the joint was emptied by a trocar and cannula of two ounces of dark bloody serum. No independent motion could then be detected between the fragments. The limb was bandaged to a posterior splint.

March 31st.—He has been more comfortable since the joint was tapped. It has not refilled. A line of separation between the fragments can be detected, but upon gentle manipulation there is no independent motion. The temperature has been normal.

April 2d.—The curved needle (see Fig. 5) was introduced into the joint on the outer side, and by its means a narrow gap of separation could be made out between the fragments, which seemed bridged over by firm tissue above. The insertion of the needle was treated as an exploratory procedure, and the existing conditions were not tampered with. A posterior splint was reapplied.

April 10th.—It is impossible to decide, without using undue force, whether the union of the fragments is bony or ligamentous. Passive motion and douching of the limb is to be practised. In flexing the limb the heel is not to be raised from the bed, and the splint is to be applied only at night.

May 5th.—The patient can bend the knee about thirty degrees. He walks about on crutches.

May 22d.—The fragments are united with very little separation. He can flex the leg to almost forty-five degrees. He was discharged from the hospital.

July 13th.—There is no separation of the fragments. It is doubtful if there be independent motion between them. He walks with a cane and can flex the leg through forty-five degrees.

February 6, 1887.—The right patella is notched on both sides at its middle. There is clearly no independent motion between the fragments, and to all appearances bony union. The line of fracture is marked by a slight ridge transversely across the bone, caused by the upper fragment having united with the lower upon a plane slightly anterior to it. The patella is slightly lengthened, being from two sixteenths to three sixteenths of an inch longer than the opposite one. There is perfect control over extension in a horizontal line. He can flex the leg to nearly right angles with the thigh. The thigh on the injured side is from one-half to three-fourths of an inch smaller in circumference than the opposite one. He has been exceedingly timid about moving the joint. After leaving the hospital he neglected following instructions about moving it; but, instead, he tried to recover motion by thrusting the limb among the warm entrails of slaughtered animals. He kept the knee bandaged, the upper turns constricting the tissues. He is directed to douche the knee daily with cold water and to be brave in attempting to move it.

Remarks.—The feature of greatest scientific interest in this case appears to me to be the fact that, on the sixteenth day after fracture, under gentle manipulation the patella moved as a whole, and there was not independent motion between the fragments.

Reflecting upon the important part played by the curtains of infolded tissue covering the fractured bony sur

faces of the fragments as an obstacle to bony union, it seemed to me that they also exerted a great influence over the character of the ligamentous union. It appeared reasonable that could the broken bony surfaces be subcutaneously denuded of these structures preventing bony contact and limiting the amount of bony surface for the formation and attachment of ligament, that it would be possible to achieve either bony or inextensile ligamentous union.

With this in mind, on August 23, 1885, in operating upon Case V., I thrust a common darning-needle, mounted in a wooden handle, into the joint, and observed through the incision that in that case, which chanced to be an extremely favorable one, I could probably have raised subcutaneously the infolded tissue from between the fragments.

To give more range to my manipulations I designed the needle shown in Fig. 4, by means of which I imagined I should be able by carefully considered systematic manœuvres to peel the fibrous tissues from the bone, and with the back of the bend of the needle thrust them from between the fragments as they were brought together.

Fig. 4.

The first case that came to my hand was the following one:

Case XIII.—Simple fracture of the patella with probable infolding of the lacerated fibrous tissue; operation at the end of two weeks of subcutaneously lifting the tissue infolded upon the fragments; a firm short ligamentous union between the fragments at the end of three weeks; ultimate recovery of good power of extension in a horizontal line, and complete flexion without lengthening of the ligamentous union.

M. C——, aged forty, laundress, was admitted into Bellevue Hospital, November 5, 1885. The patient is very intemperate. On the evening of October 26th, while intoxicated, she fell down a cellar-way a distance of fifteen feet, causing a scalp wound over the left eye and a fracture of the right patella. Before admission into Bellevue the patient had an attack of facial erysipelas, spreading from the scalp wound. Upon admission there was found beside the scalp wound a transverse fracture of the right patella, the lower fragment being very small. There was much swelling about the knee-joint, and some redness of the skin. The limb was placed upon a posterior splint and lead and opium wash applied to the joint.

November 6th.—The fragments, which are separated about three-fourths of an inch, were approximated by means of strips of rubber plaster acting upon pads properly placed in relation to the fragments.

November 8th.—Dressings removed and a Little's splint applied.

November 9th.—The Little's splint having proven unsatisfactory, it was removed this morning. The fragments were again approximated by means of adhesive plaster, and a strong plaster-of-Paris splint was applied from the ankle to the upper portion of the thigh.

Operation.—At 2.30 P.M., an opening was cut in the anterior and lateral aspect of the splint, fully exposing the knee. There was considerable swelling about the joint and over the region of the patella. A needle shaped like that shown in the cut was introduced into the joint on its outer aspect between the fragments, and in a line presumably above the level of their cartilaginous surfaces. There was so much puffiness about the joint that it was only with difficulty that the upper fragment could be recognized. The lower fragment could not be distinctly felt. The point of the needle was directed in search of the broken surface of the lower fragment and an effort was made to denude it of its fibrous tissue and raise it from between the fragments. The bone was scraped till a distinct bony grating was easily heard by the bystanders. No pain was thus far felt by the patient. The point of the needle was turned toward the upper fragment, but every prick caused severe pain and contraction of the quadriceps muscle. An hypodermic injection of ℥ viij. of Magendie's solution of morphia failed to relieve the pain of the pricking of the needle. The joint had now become so swollen that the upper fragment could only with difficulty be felt and steadied. The effort to reach the fractured surface of the upper fragment having failed, the needle was withdrawn. There was persistent venous oozing from the needle opening, which, however, was easily controlled by pressure with the tip of the finger. The needle was again introduced half an inch above the lower opening, and after some manipulation, which was painful to the patient, its end was pushed more deeply into the joint toward the femur and the fragment was reached, and then thorough scratching of its surface caused no pain. It was now clear that previously the point of the needle had not been carried deeply enough between the fragments, and that it had engaged the fibrous structure overlying the patella. Some venous oozing followed the withdrawal of the needle. The surfaces were now brought together and bony crepitus was felt for the first time since admission into the hospital. The oozing points were stopped with pledgets of iodoform gauze. The fragments, which could be brought together only with considerable force exerted through the swollen tissues, were held in place by narrow strips of old blanket saturated in plaster-of-Paris paste after the plan of Dr. Little. An ice-bag was applied to the knee.

November 10th.—The splint was cut open its whole length upon its anterior surface, and a common bandage was applied from the foot upward.

November 13th.—Urine albuminous.

November 15th.—The swelling of the joint has somewhat subsided, loosening the retaining strips of plaster of Paris; new ones were applied.

November 20th.—The plaster strips embracing both fragments were again re-applied. No attempt was made to feel the fragments.

December 1st.—The retaining plaster strips were again removed. The patella moves as a whole. Upon gentle manipulation there is no motion at the line of fracture, nor is there a sulcus between the fragments. The strips were re-applied. The highest temperature from the operation was 100.4° F.

December 12th.—The whole apparatus was removed from the limb. The patella was obscured by the œdema about it. Under moderate force of manipulation the nature of the union between the fragments was not determined. The limb was bathed in alcohol and water and the splint was re-applied.

December 24th.—The œdema about the knee is much less, and examination shows that there is about one-fourth of an inch separation between the fragments. The splint was re-applied. It was to be removed twice daily and the limb douched.

January 31, 1886.—Upon careful examination about three-eighths of an inch separation can be felt between the fragments. She is allowed to practise motion in the limb.

March 14th.—For the past two weeks, in walking about, the patient has discarded the use of crutches. She can now flex the injured knee as freely and as far as the opposite one, but she cannot perfectly extend the limb horizontally, the leg in that position forming a very slight angle with the thigh. She walks with a slight lameness, and says she has a slight weakness in the injured knee. Upon measurement there is found three-eighths of an inch separation between the fragments, the same as after the removal of the splint. She has acquired full flexion of the limb without lengthening of the ligamentous union.

February, 1887.—This patient was lost sight of, but upon inquiry it is learned that she died in the summer of 1886. There was no refracture of the patella or of the ligamentous union, and she continued to have good use of the limb till death.

Remarks.—It is to be especially noted that three weeks after the operation upon gentle trial the patella moved as a whole and that there was no independent motion between the fragments. The ligament did not stretch as motion was carried to the full extent of flexion.

This case was an extremely unfavorable one for the first experiment. The length of time that had elapsed since the fracture (thirteen days) made it probable that the fibrous tissues were quite adherent to the underlying bone; besides, the patella was very small and deeply buried. Compensative shortening of the ligamentum patellæ would no doubt take up the slack in the mechanism of extension, and remove the slight weakness of the limb due to lack of perfect extension observed while she was in the hospital.

Case XIV.—Simple fracture of the patella, from muscular action; the infolded subcutaneous tissue lifted subcutaneously three days after the receipt of injury; short ligamentous union between the fragments at the end of three weeks; ultimate recovery of full power of extension and flexion without stretching of the ligamentous union.

F. W.——, aged twenty-five, pedler, was admitted into St. Vincent's Hospital November 27, 1885. The patient has suffered from attacks of acute articular rheumatism. Some days before his present accident had pain and weakness in his left knee. Just before admission into the hospital, while feeding his horses, he slipped and fell, but does not remember striking on his knee. Upon examination there was found a simple transverse fracture of the left patella just above its middle, with slight swelling of the joint, but no ecchymosis. The limb was placed upon a posterior splint and an ice-bag was applied to the knee.

November 28th.—The joint has become swollen and painful. Ecchymosis about the joint is appearing and extending.

November 30th —The patient was prepared for wiring of the patella fragments. On account of his obesity and evidences of heart disease he is considered an unfavorable subject for etherization. There is diffused redness and pitting of the skin about the joint, and it was decided to be unwise to proceed with an operation by incision. The patient was kindly placed at my disposal by Dr. Charles Phelps for the operation of subcutaneously lifting the infolded fibrous structures. The fragments of the patella when rubbed together yielded only a sense of soft friction, without any crepitus. The needle was entered on the outer aspect of the knee in the interspace between the fragments. Its introduction was much facilitated by first dipping it in carbolized oil. The broken surfaces of the fragments were speedily and painlessly denuded of their covering of fibrous tissue, and the needle remaining still in the joint a distinct bony crepitus could be felt by placing the hand upon the leg or thigh while the fragments were being rubbed together. After the withdrawal of the needle a pledget of iodoform gauze was held against the opening, which, however, bled but little. As the needle was withdrawn the fragments were held together, and the back of the needle was swept toward the surface and across the joint in a way judged best adapted to extrude the fibrous tissue. The whole procedure occupied less than ten minutes. The fragments were held together by the fingers till all arrangements for the application of a splint were perfected, which, on account of lack of preparation, required about an hour. Finally an apparel was improvised. The limb was bandaged to a long posterior wood splint, nicely padded, and for the pressure of the fingers was substituted narrow strips of canton flannel saturated with plaster-of-Paris, crossing the knee diagonally above the upper and below the lower fragment. Pressure was then made with the thumb and fingers upon the soft plaster strips till the plaster hardened and held the adjusted fragments permanently according to the procedure invented by the late Dr. J. L. Little. Five hours afterward, to make the whole apparel more secure, a plaster-of-Paris bandage was applied over all except the region about the knee-joint. Morphia was given at night.

December 2d.—The swelling in the joint has remained about the same and the patient has complained of some pain of a gnawing character.

December 6th.—The effusion has subsided to such a degree that the plaster strips are losing their hold upon the fragments. The whole apparatus was removed and a Little's posterior splint was applied.

December 7th.—There is no pain in the joint, and the patient feels very well. The Little's splint having proven very unsatisfactory, mainly on account of the poor quality of the plaster, it was removed. The fragments were held together by strips of mole-skin plaster, acting upon suitably placed pads of lint. A plaster-of-Paris splint was applied from the ankle to the upper part of the thigh, leaving the patellar aspect of the knee uncovered.

December 20th.—The splint was cut down and removed. Upon gentle trial the patella moves laterally as a whole. There seems to be good union between the fragments, but whether it is bony or ligamentous cannot be determined. There is no sulcus between them. The highest temperature was 102° F. the night after the operation; it fell gradually to normal the seventh day.

December 28th.—The patient was transferred to his home, the limb being in the splint. Even now there is discoloration of the skin from the ecchymosis of the injury, reaching from the upper part of the thigh nearly to the ankle, posteriorly. At the time of his discharge from the hospital the patient had premonitions of rheumatism, which one week later developed into an acute attack, affecting the right knee and ankle-joints, but did not involve those joints on the left side. This attack lasted two weeks. The splint was kept on as a protection, being frequently removed for washing the limb, till ten weeks after the operation. Upon its removal there was a great deal of œdema about the knee, and the whole limb was defective in vitality. It was douched and massaged daily, but motion was not systematically commenced in the joint till about the middle of February, when the tissues had begun to regain their suppleness. The union between the fragments is by a short ligament.

April 29, 1886.—The patient has motion of the leg a little past a right angle. There has been no stretching of the ligament, which seems especially strong in the right side, the one opposite the side of puncture. For about a month he has been at work.

May 24th.—The fractured patella is about three-eighths of an inch longer than the opposite one. There is independent lateral motion between the fragments. He is able to flex the injured leg as perfectly as its healthy fellow. He can also, while sitting, extend it horizontally, but cannot hyper-extend it. This function of the joint has been regained without lengthening of the ligament. As a pedler he runs up and down stairs as well as ever, and has no pain in the knee. A while ago while walking the knee would sometimes slightly give way, and in recovering control over it he would have pain at the seat of fracture, but now he very seldom has this difficulty.

June 22d.—The patient has complete power of extension and flexion of the limb, without lengthening of the ligament, and the leg has not given way or failed him in any degree since the last note.

October 31st.—The patient still retains perfect function of his injured limb, but complains of pains in the opposite one similar to that which preceded his fracture of the left patella. These pains he attributes to an irregular action of the knee.

May 12, 1887.—The fractured patella is one-fourth of an inch longer than its fellow. There is no sulcus between the fragments. The ligament is firm. The lower edge of the fractured patella is about three-eighths of an inch nearer the tubercle of the tibia than the unbroken one. The thigh on the injured side is half an inch smaller round than the sound one.

February 10, 1890.—The patient has been constantly

at his work. There has been no change in the broken patella. The joint shows no weakness and never troubles him; functions perfect.

Remarks.—Had there been a good means of holding the fragments together after the operation, the chances of bony union would have been good. The absence of pain in the needling indicated that pain from an attack of the needle upon the tissues would show that a wrong direction had been taken. Twenty days after operation the patella upon gentle handling moved as a whole, and there was not independent motion between the fragments. The ligament did not stretch as complete flexion was gained. The weakness in the joint, due to slack in the medium of extension, disappeared under shortening of the ligamentum patellæ.

Case XV.—Simple fracture of the patella; subcutaneous lifting of the infolded fibrous tissue on the thirteenth day; failure to effect strong ligamentous union through faculty technique of the operation and imperfect retentive apparel. Operation of wiring eleven weeks after injury; tilting of lower fragment; infolded fibrous tissue; adhesions in the joint; inability to bring the fragments in apposition; firm ligamentous union without suppuration; ultimate recovery of full power of extension with nearly perfect flexion without stretching of the ligamentous union.

A. S——, aged thirty-eight, German laborer, was admitted into Bellevue Hospital, August 7, 1886. On the day of admission the patient fell on the wet deck of a steamer, striking on the left knee, which was flexed at the time. On admission the knee is somewhat swollen. There is a transverse fracture of the left patella at the junction of the lower and middle thirds of the bone, with about three-fourths of an inch of separation of the fragments, which can be brought together without crepitus. The limb is bandaged to a posterior splint and an ice-cap is applied to the knee.

August 19th.—The knee is somewhat swollen and ecchymosed. The fragments, which are freely movable, can be brought together, but give no crepitus.

August 20th.—The fragments when rubbed together fail to yield crepitus. The knee-joint has been considerably reduced in size by bandaging, the knee having been first wrapped in cotton batting.

Operation.—The bent needle was introduced opposite the interval of separation on the outer side of the joint, and the fractured surface of the lower fragment was easily reached and scratched without any pain. The needle was then directed to the upper fragment and its fractured surface operated upon. This manipulation caused a moderate amount of pain and swelling of the joint and reddening of the skin over the anterior aspect of the knee. After less than ten minutes of manipulation the needle was withdrawn. Venous blood oozed freely from the needle-hole, but was checked by an iodoform compress. The fragments, when rubbed together, produced bony crepitus. No special efforts were made to hold the fragments together after they had been operated upon till permanent fixation apparatus was adjusted. Then a pad of lint was placed below the lower and one above the upper, and by means of strips of adhesive plaster diagonally applied the fragments were held in position. A posterior splint was applied, the turns of the bandage being made to act upon the fragments by embracing them in a figure of 8, leaving the anterior aspect of the patella free.

August 21st.—Skin over the patella is somewhat reddened. There is some heat and pain in the joint, which remains swollen.

August 22d.—Swelling of the joint diminishing; no pain.

August 24th.—Swelling has diminished very much; a new bandage is applied over the old one, which has become loosened, the region over the patella anteriorly being left free.

August 28th.—As the swelling has receded new bandages have been tightly applied over the old ones.

August 30th.—Another bandage applied over those already upon the knee, the region of the patella anteriorly being left exposed.

September 3d.—Outer bandage removed and re-applied.

September 4th.—The bandage was so tightly applied as to cause considerable swelling of the exposed portion of the knee. Cotton batting was wrapped about the knee, which was then bandaged.

September 17th.—All bandages were removed. The patella fragments are laterally easily movable independently and are separated about half an inch, the separation being greater on the outer than the inner side. There is no sulcus anteriorly between the fragments. The limb was placed on a posterior splint.

November 1.—Under passive motion, which was carefully begun six weeks after the operation, the ligamentous union has perceptibly stretched, although motion has not been made through more than twenty degrees. For the past week the fragments have been brought together by means of pieces of adhesive plaster fastened to the anterior surface of the leg and thigh and buckled together. When this appliance is removed the fragments remain about three-fourths of an inch apart. The tissues about the knee are much infiltrated.

Operation.—To-day the knee-joint was opened by the usual transverse incision, under continuous irrigation with 1 to 4,000 bichloride of mercury solution. The incision being deepened encountered thickened fibrous tissue extending between the upper surfaces of the fragments but not between their broken bony surfaces. This tissue being cut through the lower fragment came into view. It was so tilted that its fractured surface looked directly forward, its cartilage presenting toward the upper fragment. The superficial bony edge of this fragment was found somewhat encroached upon by fibrous tissue, which was then pushed off by a sharp spoon. The fractured surface of the upper fragment was not tilted, but was partly covered with infolded tissue and granulations. The extension to approximate the fragments seemed to have acted upon the overlying fibrous tissues rather than upon the bone itself, leaving the upper fragment when exposed at the bottom of a cup of fibrous tissue. A distinct membrane extended from the lower edge of the upper fragment to the anterior aspect of the femur, partitioning off the synovial pouch. The end of the large probe being passed behind this membrane at the outer side of the joint, could be freely swept about in the synovial pouch, which was of normal dimensions and without other adhesions. An incision for drainage was made in the usual location. Strongly adherent fibrous tissue encroaching upon the fractured surface of the upper fragment was peeled off, and a dense layer of underlying bone was cut away with the Hebra's scoop till the cancellous structure was reached. Upon the fractured surface of the lower fragment there was less infolded fibrous tissue, and the surface of the bone had not become dense but retained its spongy structure. The upper fragment was drilled in the usual way. As the lower fragment could not be drilled without considerable dissection on account of the thickened and inelastic soft parts, the drill was carried through all the covering soft parts and then through the bone. The end of the wire having been drawn through the lower fragment and soft parts the drill was entered at the place of emergence of the wire and carried superficially to the bone along the destined course of the wire. By means of a loop of silk drawn along the path of the drill the wire was pulled into proper position. The fragments could be brought together only by their lower edges, and the wire was twisted, leaving them separated by an interval of about half an inch at their upper edges. This difficulty of adjustment was due in great measure to the tilting of the lower fragment and the general rigidity of all the soft parts. The twisted wire was cut short. The fibrous structures anterior to the wired fragments were sewed together with continuous catgut suture, and the skin wound closed by interrupted silk sutures. In ad-

dition to the insertion of a drainage-tube at the place of election, the dependent angles of the wound were left quite open for drainage.

November 6th.—The drainage-tube was removed through an opening made in the outer side of the dressings.

November 16th.—The dressings were removed for the first time. There is union of the wound by first intention except at the angles, which are filled with healthy granulations. The interrupted sutures were removed. The temperature has been normal since the fourth day after the operation.

December 24th.—The posterior splint is used only at night and removed during the day. The patient practises motion in the joint without lifting the heel from the bed. There is some œdema about the joint.

January 7, 1887.—The patient is out of bed and has motion to twenty degrees.

January 17th.— Motion to forty-five degrees.

January 25th.—The splint is removed altogether.

March 1st.—To-day the patient was discharged from the hospital. He has acquired motion to nearly a right angle without any further separation of the fragments. He has good power of extending the limb horizontally. The range of flexion is daily increasing. The tissues about the knee are quite supple. There is still some œdema of the leg.

November 4th.—The patient has had no accident to the patella since the last note. He has recently been in the hospital for the treatment of a varicose ulcer on the left leg. The fragments of the fractured patella are separated three-fourths of an inch, and are independently freely movable laterally. They are united by a strong ligament, the upper surface of which is flush with the upper surface of the fragments. The wire cannot be felt, nor has its presence caused irritation. The lower edge of the lower fragment is three-fourths of an inch nearer the tubercle of the tibia than the corresponding edge of the opposite one. The thighs above the knees have the same circumference. There is complete power of extension of the limb in a horizontal line, although the leg is weighted with œdema. It can be flexed past a right angle to very nearly the extent of the opposite one. The patient can kneel upon the floor. The joint has never given way since the operation. With the hand upon the patella, a grating sensation can be felt when the leg is flexed.

Remarks.—In this operation I worked upon the thought that blood collecting in the joint would float the loosened fibrous tissue and hold it clear from the broken surfaces of the bones. It was inefficient. The length of time after the accident gave to the infolded structure a rigidity that was unfavorable to success. Four weeks after the subcutaneous operation, the fragments were freely movable laterally upon one another, and the ligamentous union was very extensile. The tilting of the lower fragment and the adhesion of the upper fragment to the femur were due to the retaining bandages. When by the open method the fragments were denuded of infolded tissue upon their broken surfaces, the ligamentous union, as in Case I., was firm and inextensile, with consequent perfect extension and nearly perfect flexion ; this function being gained in spite of the undisturbed adhesion of the upper fragment found at the time of operation.

Case XVI.—A. E. F——, aged fifty-two, on October 14, 1888, while climbing over a stone wall fell and struck upon his left knee and as he rolled over and over felt the patella part. The knee was much swollen after the accident. A few days later I saw him in consultation with his physician, Dr. Sarah E. Post. The knee was very much swollen, but a transverse fracture of the patella at its middle could be made out. The patient was very weak, being unable to sit up in bed on account of contusions of the body. Although no fracture of the rib could be detected a spot of inflammation at the base of the right lung was diagnosed. His expectoration was tinged with blood, the urine contained sugar, and his general condition forbade the use of an anæsthetic or the performance of an important operation. He was very anxious to have the broken patella wired, but I declined to operate and proposed as a substitute the subcutaneous procedure, which was accepted.

To overcome some of the obstacles I had met with in the other operations of this character, especially the annoyance of blood accumulating in the joint, I planned to operate somewhat differently than heretofore.

Operation, two weeks after the accident.—All the preparations were as antiseptically made as for the open operation of suture. The knee-joint was still distended and the surrounding tissues swollen. After elevation of the limb a rubber bandage was applied about the region of the joint, leaving free its anterior aspect and a sufficient field for operation. The turns of the bandage were fastened at the lower third of the thigh. About twenty minims of a four per cent. solution of cocaine were hypodermically injected upon the fibrous tissue at the middle of the edge of the upper fragment. A small trocar and cannula were introduced into the joint, at its outer side, between the fragments. Although the joint was partially under elastic compression, only a small amount of bloody serum and no clot came through the cannula. With a very small and narrow-bladed tenotome I pierced the skin just above the lower edge of the upper fragment and tried to split to the bone in the median line any fibrous tissue that might be infolded over the upper fragment. Without withdrawing the blade a firm incision to the bone was in like manner made through any fibrous tissue that might overlie the lower fragment. Through the very slight opening in the skin oozed about one ounce of dark semi-solid clot upon the withdrawal of the knife. Through the cannula was now passed the straight stylet shown in Fig. 5. The end of which was so grooved as to form three teeth (shown in the end view at *b*), by means of which it could in any position bite upon the infolded fibrous tissue. The end was squared on its face, so as to give a good surface for pushing. After trying to free the broken surfaces of infolded tissue, the openings made by the knife and trocar were stopped with iodoform gauze compresses, and the fragments, from which upon friction together some crepitus was now obtainable, were held together by strips of adhesive plaster. An antiseptic dressing was applied about the knee-joint and the limb was bandaged to a posterior splint. The carrying out of the details of the operation was bothersome and in the aggregate consumed a good deal of time. The patient complained of considerable pain from the prolonged constriction of the elastic bandage. After the operation there was some oozing into the dressings from the tenotome cut. There was no reaction in the joint of any importance.

Fig. 5.

At the end of four weeks, when the splint was removed, the fragments were found about one-fourth or three-eighths of an inch apart, as well as could be judged through the somewhat œdematous tissues. While the fragments were laterally independently movable yet there was enough resistance to lead me to predict that the ligamentous union would be a serviceable one. No motion was begun till two months after the operation. Then the tissues about the joint were still much swollen. As the œdema in the limb, which on account of the patient's feeble general condition was persistent, gradually subsided, he increased his efforts to move the joint.

Sixteen months after the injury, upon examination there is found a firm ligamentous union one-half inch long. According to the patient's statement, and he is an intelligent man, and my own observation, the ligament has not stretched as motion has been gained in the joint. The lateral motion of the patella is not quite so free as that of its fellow. There is complete power of extension

and flexion through fifty degrees. He is still gaining slowly in the power of flexion. There is yet, after standing much, some œdema about the knee and ankle.

From the cases in which I have tried the operation the conclusion seems justifiable that with the bent needle the chance is increased of producing a strong inextensile ligament by subcutaneously lifting the infolded tissues. The procedure requires more skill than would be first imagined. Its successful range of application is limited by a number of conditions. It is impossible for the most sensitive hand to tell by means of the needle the exact state of the interior of the joint as regards the infolded tissue. It may be so wrapped over the surface of a fragment, as in Case No. IV., or otherwise so peculiarly disposed, that it would be impossible to extrude it from between the fragments. The combination of conditions favorable to success are: Absence of swelling in the joint; no comminution of the fragments; a simple and usual infolding of the tissue, and early operation before the torn structures have become rigid in a shape unfavorable to their mechanical displacement; to which may be added the feasibility of successfully holding the fragments together after the operation.

On the other hand, the narrated cases of the operation, I think, support the proposition that the infolded tissues are an important disturbing factor in the formation of the ligamentous union as regards its extensibility.

Among the instances of suturing the patella narrated in this paper, which comprises all my cases, there has not been one case of suppuration or other septic mishap. Most of the operations were conducted in hospital wards known to be infected; where, before the use of antiseptics, pyæmia was very prevalent, and where the walls have still a poisonous influence, as was shown during the period of these operations, through occasional lapses in antiseptic treatment.

The instances of the operation are sufficiently numerous, and the septic influence of the surroundings of such proven intensity to warrant the inference that the freedom from suppuration, or any septic complication whatever, was due to the definite group of conditions described as antiseptic measures. This inference is further strengthened by the very strong presumption in its favor, drawn from a consideration of the favorable influence of antiseptic conditions upon the results in the treatment of other wounds, especially in the wards of Bellevue Hospital.

The instances of successful suturing of recent simple fractures of the patella in hospital practice have now become so numerous that they, as it appears to me, justify the conclusion that antiseptic measures are competent in all cases of the operation to prevent septic complications that endanger the limb or life of the patient.

Since opinion of the safety of the operation has been unfavorably affected by instances of septic mishaps, especially when they have occurred in the hands of surgeons of repute, it is proper to examine the logical force of such cases in limitation or denial of the conclusion advanced. To have logical force each case must be regarded, at least by implication, as a denial that in that specific instance and others of like kind, a fortunate result would have followed under those conditions prescribed as necessary to success. It is an endeavor to prove the existence of exceptions in which antiseptic measures are ineffectual to avert sepsis. The difficulties of the proof are obvious. How are the exceptions to be defined? The range of constitutional and local conditions included in the successful instances is so exhaustive as to remove distinctive marks for definition. It is to be noted that a single successful instance in an asserted class of exceptions, destroys the denial which it is sought to prove regarding that class. The formation of a group of exceptions presupposes that not only have certain antiseptic measures been inoperative in those instances, but, further, that the antiseptic measures effectual against the strongest exposure to infection would have failed. Till these conditions of disproof are fulfilled it is safe to assert, in view of the many successful instances of the operation, that the mishaps have not been due to the existence of any actual exceptions to the favorable influence of the antiseptic measures, but rather to defective application of those means, or, in other words, to the accidental substitution of other conditions for those of antiseptic power. The failure, then, is not in the antiseptic method itself but in its application, and this is a defect in skill, and skill is a personal factor. I have known of an authority upon the subject, in the application of a simple apparel to a simple fracture, causing the death of his patient. This was due to a lapse in skill, and is no argument against the skilful application of splints. In the non-operative treatment of this very injury most serious accidents have sometimes followed the use of comparatively simple apparel, but this is no argument against the skilful and proper use of such appliances. Of the danger attending the substitution, accidentally or wilfully, of other conditions for those antiseptic measures of proven efficiency, especially in the face of strong liability of infection, there can be no question. While it is safe to suture the broken patella under the conditions that have been detailed it is highly dangerous to break down the guard against sepsis by failing to control the realization of those conditions. The argument to be drawn from the failures of antisepsis in the operation is against defective skill, and emphasizes the importance of the personal factor in insuring safety. I am quite sure that I have been present at operations when the factor of safety has been a small one, and the continuous irrigation with an effective antiseptic solution prevented the failure of the operation.

There remain for consideration certain accidents that may be connected with the method. There may be danger from the anæsthetic one of the elements of the operative procedure. Patients to whom it would be dangerous to give an anæsthetic should be excluded, or perhaps the operation might be performed with some substitute for the ether.

There is also a rare condition of irritability of the tissues in debilitated constitutions, wherein, although there may be no sepsis, the soft parts are very reluctant to heal, and resent even the tension of the stitches. In such a patient, while the bones might be wired together, the incised soft parts would certainly have to slowly heal as an open wound. The chances of these accidents, which, indeed, are not accidents but inevitable consequences of constitutional states of the patient, limit somewhat the range of application of the operation.

Most probably in all cases a bichloride solution, even as weak as 1 to 4,000, is sufficiently irritative to cause adhesions in the joint. But, as has been shown, these adhesions under intelligent treatment of the joint are not incompatible with the restoration of full function.

While the wire suture properly placed remains perfectly quiescent and without deleterious effect upon the bone, yet the use of the metallic suture is attended with a risk in case of a refracture of the bone and loosening of the suture. Then the patient would be committed to another operation, and perhaps under adverse circumstances. This risk, which is peculiar to the retained wire suture, can be eliminated by the early removal of the wire, or, what is better, by the use of a soft or absorbable suture, instead.

The liability of refracture after suturing has been shown by two instances. This accident could have been prevented in each had the limit in the range of flexion been controlled by a proper appliance worn by the patient. Refracture before the skin has become supple and while the tender scar is still adherent, exposes the patient to a great risk of the joint being opened by a laceration of the soft parts. This liability, which, though not peculiar to the operative method, is much greater than in the non-operative method, lessens as the soft parts approach their normal condition, and the scar becomes movable.

The internal condition of the joints after simple transverse fracture of the patella, as disclosed by these operations, confirms in the main the original observations of Dr. William MacEwen, of Glasgow, and the conclusion so ably urged by that surgeon, that the obstacle to bony union under non-operative methods of treatment is generally the infolded fringes of fibrous tissue covering more or less completely the broken surfaces of the fragments. No method of treatment that does not accurately recognize and correct this interior condition of the joint can hope with any uniform measure of success to secure bony union of the fragments.

Not only do the infolded fibrous tissues play such an important part in reference to bony union, but it seems to me that they have an important influence in determining the character of the ligamentous union. It will be noted in the narrated instances of ligamentous union, that in proportion as the broken bony surfaces have been freed of intervening structures has the ligament been strong and inextensile. No matter how uniformly a method of treatment holds the fragments in apposition, the presence of this infolded tissue over a variable extent of their broken surfaces is a variable factor that disturbs the uniformity of the results so far as the extensile character of the ligamentous union is concerned.

The suturing of the fragments in cases of recent simple transverse fractures of the patella by the open operation affords an opportunity for exact recognition and rectification of the disturbed interior conditions of the joint. It is an operation (conducted under the definite antiseptic measures detailed as an essential part of the operation) that is practically safe from septic complications. The remote risks attending the permanent wire suture are special to that suture and may be eliminated by using other material. The risks from unfavorable constitutional conditions of the patient are those common to all operations, and may be excluded by limiting the range of applicability of the operation. The risks of refracture are not peculiar to this operation except in the greater liability of the refracture being a compound one, and are probably preventable by a proper protective apparel. In the vast majority of cases bony union can be obtained, and in those cases where the fragments cannot be brought into contact but near together a firm and inextensile ligamentous union can be achieved. The joint is so perfectly reconstructed that in case of refracture the patella stands in the same relation to treatment as in the primary operation and the repeated operation will again restore its function.

Under non-operative methods of treatment bony union is a surgical curiosity. In a hospital experience of nearly twenty years I have seen but one instance of bony union, and that was under circumstances that lend support to the view of the importance of the infolded torn prepatellar structures as an obstacle to bony union. The surgeon attempted to break up a fibrous anchylosis of the knee-joint caused by long confinement in a plaster-of-Paris splint. Upon forced flexion the patella broke transversely at the middle. The limb was extended and immediately encased in a plaster splint. Bony union resulted. The fibrous tissues over the patella had lost their elasticity, and most probably tore in the plane of the bony fracture without infolding. In the vast majority of cases, as is well known, the union is ligamentous, the character of the ligament being determined by unrecognized interior conditions of the joint. Thus it happens that in one instance the ligament is serviceable, in another it stretches and leads to crippling of the limb.

In comparing the results after the operative and non-operative methods it is to be noted that motion in the joint has not the same value throughout the whole range of flexion and extension; thus, flexion and extension of the leg from the line of complete extension is vastly more important through the first forty-five degrees than from that angle through the next forty-five degrees to a right angle with the thigh. This is understood when we reflect that in locomotion, the limb with some motion at the joint becomes an uncertain means of support unless the leg can be so extended as to bring the line of support of the limb very near or anterior to the axis of motion in the joint, thus, as it were, locking the joint while the limb bears the weight of the body. After suture by open operation the integrity of the mechanism of extension is restored, and there is no loss in the power of extension and consequent impairment of the limb as a medium of support. With a ligamentous union it is otherwise. Then there is loss in the power of complete extension in proportion to the length of the ligament, and, at least, a temporary instability of the limb. This weakness is a constant menace in the early weeks of motion to the integrity of the ligamentous union. Later, the slack in the tissues through which extension is exerted is taken up more or less completely by the shortening of the ligamentum patellæ, and perhaps also, in part, by an accommodative action of the great extensor muscle acting in part through hypertrophied lateral fibres of its aponeurotic expansion.

The comparative value of the function of the joint after the operative and non-operative treatment is best shown by a comparison of the functional possibilities of the joints rather than by a study of the events in their subsequent functional histories. Thus, an accident potentially present in a weak joint may not be displayed till called forth by circumstances years later, as in the case of M. C——, who, in 1871, was treated in Bellevue Hospital for simple transverse fracture of the right patella by an approved non-operative method. There resulted a weak ligament, which stretched under flexion of the leg till the limb became so crippled that the patient was obliged to abandon his occupation as a longshoreman, and, in 1885, fourteen years later, it was the cause of a fall in which he broke the tibia and fibula, two inches and a half above the ankle-joint.

After open operation and suture, in a short time and with certainty, the joint is restored to its former function in at least its most important elements A limitation to the range of motion is in that of flexion, and for this the patients themselves are generally responsible. They are so well satisfied to walk securely and gain the range of motion demanded by the ordinary affairs of life, that they sometimes fail to appreciate the necessity of pushing flexion to its full limit, and thereby secure perfect protection from an accident due even to the slightest incapacity of the joint.

If a ligamentous union stretches to that extent that the slack in the mechanism of extension cannot be taken up, then there is permanent crippling of the limb, consequent limitation of function, and liability to accidents.

It is the duty of the surgeon, I conceive, according to his ability, to treat his patient by that method which yields the best results. The value of a method of treatment is not to be determined by reference to the fluctuating standard of professional opinion, but by the comparison of the results of treatment to a single and invariable standard of perfection. The standard I have had in mind, in comparing the results of the operative and non-operative methods, has been the restoration of the function of the injured joint in the shortest time. From the comparison of the results obtained by the two methods, I therefore believe it to be the duty of the surgeon, in a case of recent simple transverse fracture of the patella (adequate skill being granted, and subject to the qualifications already expressed), to open the joint, and suture the broken fragments, unless he can insure his patient a good result by the non-operative method, with freedom from crippling of the limb and the other disabilities potentially belonging to an imperfectly reconstructed knee-joint.

The non-operative method of treatment, it appears to me, should be restricted to those cases of fracture in which there can be obtained either bony union or a short inextensile ligamentous union. The interior conditions of the joint essential to the production of this result are present in only a small minority of cases. To extend the ap-

plication of this method beyond these limits is to violate that principle which I have premised should govern the conduct of the surgeon. From this point of view, it is of paramount importance to be able to foretell what will be the character of the ligamentous union.

Upon *a priori* grounds, and from a study of the cases of ligamentous union narrated in this paper, it would appear that the early firmness of the ligamentous union affords some criterion of its later character as regards extensibility. It has seemed to me that a test of the independent lateral mobility of the fragments at the end of two or three weeks shows the nature of the forming ligament. When the fragments move as one mass and not freely, independently, the forming bond of union may be surmised to have the attributes of strength and comparative inextensibility. In a limited number of cases the subcutaneous lifting of the infolded fibrous tissues may be the means of favorably influencing the character of the ligament. I am aware that this is setting up a test based upon nice discriminations in the sense of touch and not easy of definition. However, it is a line of investigation that, it appears to me, is necessary to be further prosecuted to aid in determining the limits of the range of applicability of the non-operative and, by consequence, of the operative method of treatment.

INFLAMMATION OF TENON'S CAPSULE AS A RESULT OF INFLUENZA.

By A. SCHAPRINGER, M.D.,

Ophthalmic Surgeon to the German Dispensary and to the Eastern Dispensary, New York.

On February 25, 1890, I was asked by Dr. C. W. Allen, my colleague at the Eastern Dispensary, to see a patient with him, whose right visual organ was the seat of an inflammatory affection of unusual severity. The case was that of a young man, twenty-three years of age, born in New York City, of German parentage, who lived in an East side down-town tenement house, surrounded by unhygienic conditions, and who had been a sufferer from pulmonary consumption for a considerable space of time. We found the patient sitting up in a chair. His left eye was normal in every respect. The upper eyelid of the right eye was red and very much swollen. The swelling extended beyond the eyebrow and was most prominent upon the temporal side. The lower lid was also red and swollen but not so markedly as the upper. The conjunctiva was in a state of intense chemosis, the mucous membrane covering the globe being raised in fleshy and hyperæmic folds which protruded like polypoid excrescences between the lids and prevented their closure. The globe of this eye was slightly, but unmistakably, more prominent than its fellow. The cornea was clear, the pupil rather dilated and not responsive to light. The iris was discolored and dull. On ophthalmoscopic examination a red reflex could be obtained from all parts of the background, but no details could be made out, on account of the haziness of the vitreous body, except that the borders of the optic disk seemed not well defined. With this eye the patient could only distinguish light and dark, but could not even count fingers.

On testing the motility of the eyeball, it was found that, while the left globe moved freely in every direction, the right globe did not accompany it in its movements, but remained almost stationary. No movement at all could be produced in the upward direction, and the excursions inward, outward, and downward were quite inconspicuous.

To judge from the general behavior of the patient, the amount of distress occasioned by the deep-seated inflammatory action causing the symptoms just detailed was by far not so severe as one would have expected under the circumstances.

These symptoms were caused by an inflammation of Tenon's capsule, a structure bearing somewhat similar relations to the globe of the eye as the tunica vaginalis bears to the testicle. This capsule is opened and entered into with instruments every time when a tenotomy is performed for strabismus, and, in pre-antiseptic times at least, such tenotomy has sometimes been followed by an unwelcome attack of tenonitis, an accident not at all dreaded any more nowadays by antiseptic operators. No tenotomy or other operation had been performed in the case of our patient, nor was there a history of traumatism of any sort. There were no signs pointing to a carious affection of the bones of the orbit, especially no symptoms indicative of disease of the nasal fossæ. The irido-choroiditis present at the time of our examination—as evinced by the color of the iris, the immobility of the pupil, and the haziness of the vitreous—was evidently not the primary trouble, as the patient never had any trouble with his eye before the present attack, and the very onset of this attack, according to the statement of the patient, had been characterized by the extreme swelling of the adnexa of the globe.

The inflammation of Tenon's capsule present was evidently of the more severe or suppurative variety. No distant focus could be detected which could have caused the mischief by metastatic infection, unless we sought for such a source in the diseased lungs. As a matter of fact not a single case has as yet been recorded in which tenonitis had been caused by tuberculosis, so that this causative element could not seriously be thought of. The patient could not give a history of severe exposure either. For the reasons enumerated we were compelled to leave the question of etiology in abeyance.

The necessity of operative interference being imminent and the domestic surroundings of the patient very unfavorable for successfully carrying out surgical procedures, he was provided with a permit for admission to one of the city hospitals. However, he never turned up at the hospital to which he was sent, and I did not hear of him for a considerable space of time.

On May 1, 1890, I received a reprint of a paper on "Tenonitis after Influenza," by Professor Ernst Fuchs, of Vienna,[1] which the courteous author had sent me and which threw considerable light on a subject which heretofore had been aggravatingly dark to me. Fuchs here describes four cases of tenonitis, one of which led to suppuration and the destruction of the power of vision, while the other three were of a sero-plastic nature and ended with perfect recovery. All of these cases were observed by him during the recent epidemic of influenza.

On May 5th I paid a visit to the home of Adam G——, the patient whom I had seen with Dr. Allen. I found him in bed and his general appearance bore evidence that his pulmonary complaint had been making rapid progress since I had first seen him. Upon being questioned, the patient and his family averred that toward the end of December he had had an attack of the grip. It must be here confessed that neither Dr. Allen nor myself had thought of inquiring about this point at the time of our common visit. The trouble with the right eye had begun in the earlier part of January. He did not go to the hospital to which he had been directed. A few days after we had seen him, and after he had diligently poulticed the eye, he repaired to the office of a down-town practitioner who made an incision above the eyebrow, but the swelling did not subside. A short time after this the patient did go to a hospital, but not the one to which he had been directed. Here he was etherized and incision made below the eyebrow, which gave exit to a considerable amount of pus. He left the hospital after a week's stay. I saw the scars caused by the two incisions spoken of, which had healed perfectly. The dimensions of both the upper and lower lids of the affected eye were nearly normal. There was still some chemosis of the lower

[1] Wiener klin. Wochenschr., 1890, No. 11.

part of the conjunctiva, causing an ectropion of the lower lid. The rest of the conjunctiva was nearly normal. The lower part of the cornea was the seat of an extensive opacity which involved only the superficial layers. The iris was somewhat more dull and discolored than at my first visit. The pupil was large and immovable. A certain degree of exophthalmos was still noticeable, and the great impairment of the mobility of the eyeball noted over two months ago was still present, the excursions of the globe being perhaps a trifle more extensive. On illuminating the background with the ophthalmoscope some filiform posterior synechiæ became visible. A red reflex could still be obtained from all parts of the fundus, but no details could be made out. This examination was greatly interfered with by the opacity of the lower part of the cornea. The use of a mydriatic was not permitted by the patient. He could distinguish light from dark and could count fingers at the distance of one foot only.

The history of a preceding attack of influenza, though only given by the patient himself and his family and not confirmed by medical observation, is the only tangible etiological factor in this case. I might say here that the patient himself did not surmise any connection between his attack of the grip and the subsequent inflammation of his eye.

In two of Professor Fuchs' cases, the suppurative one and one of the three non-suppurative cases, there was a distinct history of influenza. The two other non-suppurative cases gave no such history, but Fuchs nevertheless does not hesitate to describe them as an effect of this epidemic disease, because primary, non-traumatic tenonitis is otherwise an extremely rare affection and there was no other way to account for the crowding of such a considerable number in a surprisingly short space of time, and this just the time of the prevalence of the grip.

In the single case of Professor Fuchs which led to suppuration, the pneumococcus of Fraenkel and Weichselbaum could be cultivated from the secretions.

Since the above was written, through inquiries made at the hospital, it was learned that at the time the incision was performed there was great swelling of the parts and considerable protrusion of the globe. Though pus was expected and searched for, none was encountered. The swelling and the protrusion of the globe subsided rapidly in consequence of the incision.

The first of the three non-suppurative cases reported by Fuchs bears a striking resemblance to the one detailed above. Fuchs surmised beginning phlegmon of the orbital cellular tissue or retrobular abscess, and made an incision through the upper lid, penetrating between the roof of the orbital cavity and the globe of the eye as far as the posterior portion of the orbit, but no pus was forthcoming. The patient recovered rapidly and without loss of vision.

There is an essential difference between the case observed by myself and the three non-suppurative cases of Professor Fuchs, inasmuch as in none of the latter did the intra-ocular tissues become affected in any way.

130 East Fifty-ninth Street.

A Valuable Remedy for Brain-workers.—We have received several inquiries concerning a much advertised secret remedy which has found great favor among the clergy in the West, possibly because they have a percentage on all the custom which they can bring to the "professor." The remedy is sent, on the receipt of a pledge of secrecy, to anyone for the trifling sum of $10, $6 of which is given to the clergyman who secures the order. Sometimes it is the clergyman himself who is sold. A correspondent of the *Medical Standard* says that the remedy is nothing more or less than a daily enema of two gallons of water, "persistence in which," the accompanying pamphlet says, will remove the microbes of the intestinal tract from the stomach down."

STERILIZATION OF WATER.

By CHARLES G. CURRIER, M.D.,
NEW YORK.

As practical physicians we are constantly encountering more or less serious forms of disease that we feel justified in ascribing to the pernicious influence of bacteria, conveyed by and for a long time remaining actively alive in drinking-water. A sufficient number of reliable laboratory experiments bears us out in this view, and the instances where the cause of various attacks of typhoid, cholera and less severe diarrhœal disorders lay in the use of infected waters would make an unpleasantly long list. The lessons derived from one epidemic do not stay the next one as effectively as we could hope; yet when such a danger has directly shown itself, the laity are for the moment ready to have its portent revealed to them. So it behooves us as practitioners to know just what we should counsel in order to insure the arrest, if we are not allowed to cause the prevention, of such seemingly inexcusable epidemics as the recent one of typhoid at Cumberland on the Potomac. Although the truth is gradually gaining currency that it is in general safest to consume water and milk like other foods, after—rather than before—cooking them, still most persons regard water when cooked as less palatable than before the process has taken place, and adopt various other means to secure immunity from the diseases which impure water can unquestionably carry with it. To insure the desired result we must, as I have elsewhere shown at greater length, rely upon high temperatures. Even the familiar employment of carbonic acid gas does not render water from an impure source safe unless—as part of the process—the water has been adequately purified, and for this I would only advise heating. In continuing, during the past year, my examinations of numerous samples of different carbonated waters from various sources, I have repeatedly observed that some kinds of bacteria could actually increase to a certain degree in water charged with carbonic acid gas under a pressure of over one hundred pounds to the square inch. As for the original bacteria (whether harmless or harmful) in such "soda-waters," they tend to die off more rapidly when the gaseous element is present under the usual conditions than when these germs are in simple water. Thus the process affords some advantages; but the action is too slow and uncertain to allow us to recommend the use of an impure water which has simply been charged with some salts and with the gas.

The presence of a small proportion of alcohol, or of certain other chemicals, may arrest the development of some varieties of micro-organisms; but they are an unsafe reliance, as in any reasonable strength they do not destroy bacteria sufficiently to warrant their use in preference to the employment of heat.

While testing samples of water sent from various regions, I had—as a matter of separate interest—for some time been accustomed to make experiments to determine the number of minutes required of exposure to the heat of boiling water, in order to sterilize the very different natural waters which reached me for examination. In a paper, which appeared in the *Medical News* of April 20 and 27, 1889, the then results were given as ground for stating that boiling, for even less than a quarter of an hour, could be regarded as sufficient, even if the water were from an infected supply.

The interesting articles of fleet-surgeon Globig and others led me to surmise, however, that possibly the various kinds of bacteria found in the natural waters of this continent, or such species as (in the laboratory) were experimentally introduced because of their reputed great vitality, offered less resistance to the influence of the heat of boiling than did the bacteria procurable in and near the Hygienic Institute in Berlin. Accordingly, last summer, by the great kindness and courtesy of Privycouncillor Professor Koch, and of Dr. C. Fraenkel, I availed myself of the facilities of their laboratories and pursued

a series of experiments with materials, supplies, and facilities quite like those previously employed in the same place and at the same time of the year by Dr. Globig. By his courtesy, I also received from him some of his most resistant bacilli.

Previous to, and in general since my Berlin experiments, my usage has been, after testing it cold, to heat the test-water in a number of sterilized, plugged Erlenmeyer flasks. At definite intervals, single ones of these were, by threads, rapidly removed from the steam-sterilizer in which they were being heated. Then samples were at once tested, as also after the lapse of several hours and again after several days. If, within a week, no colonies appeared in the nutrient gelatine of the plates and roll-tubes to which the water had been added, the sample was pronounced sterilized. The bacilli of tuberculosis never grew on the gelatine, and the usual animal inoculations were required to determine their presence. For the tests made in Berlin, the water was generally heated in large flasks plugged with cotton and sterilized, then these were suspended in water kept at the uniform temperature of 99° C. to 100° C. (212° F.). At intervals of two minutes a cubic centimetre was carefully removed from the top and lower middle portion of the contents of the flask, and at once added to warmed gelatine which was then spread on a cool surface.

My earliest tests were, as I have said, of clear natural waters from hydrants and other supplies. Finding that a very few minutes of steam heat sufficed to completely sterilize these, harmful and harmless varieties of bacteria were added from pure cultures, the microscope being employed to determine the presence of spores. To remove sediment, and yet have the micro-organisms remain in the water, it was strained through thin layers of sand, or of absorbent cotton. The prepared water was always tested before heating.

Not enough experiments have been made to determine precisely how the bacillus of tuberculosis changes its character and vitality when present for any time in clear water. It is within the limits of safety, however, to declare that under such circumstances boiling for ten minutes will have sterilized a given water as far as the tubercle bacilli contained in it are concerned. Anthrax spores are generally regarded as the most resistant of the disease-producing bacteria, and these I have by repeated experiments found to succumb, when in clear water, by heating at a steam temperature for five minutes or less. Kitasato has recently stated the same thing concerning the anaërobic germs of symptomatic charbon (*Rauschbrand*). The majority of harmful micro-organisms are much more sensitive, and the pus producing ones are especially so. Thus the typhoid bacilli, like the various pus-cocci, do not survive after the water has been brought to the boiling point or near that, and allowed to cool gradually. Cholera germs are still more sensitive. To render them harmless a momentary exposure to a temperature of 70° C (158° F.) suffices. Hence we may say that if a suspected water be heated at the boiling temperature (or nearly that) for ten minutes, we have allowed more than time enough to insure the destruction of all germs recognized as harmful that may be in it.

From many tests I have been led to believe that the bacteria of ordinary clear hydrant water are likewise destroyed in this same time. When I, last June (1889), stated to Professor Koch that with a clear water containing *B. subtilis* much less time was needed than tradition allowed for them to perish by boiling, he expressed himself as disagreeing with me. His criticism was of course of extreme weight, and caused me to have made many experiments before I now allow myself to assert that, in water which has been strained clear, even though containing much organic matter in solution, the various micro-organisms are usually killed by boiling for even less than fifteen minutes. Some of the natural waters which I tested contained *B. subtilis*.

Finding that heating suppressed thus quickly the many bacteria which throve in water supplied by various hydrants, I added, as I have said, putrefying solutions of meat, earths, vegetables, and other things, which might add bacteria, besides introducing from pure cultures all kinds of resistant and harmful germs, and thus endeavored to produce the worst possible waters. These were strained just sufficiently to remove the sediment and leave the bacteria. With these waters I have usually found that the limit of twenty minutes was rarely passed, except that one long bacillus, such as I have never recognized in our natural waters, withstood the heat for a considerably longer time. Even of these, only a few remained alive after fifteen minutes. A very few solitary ones usually kept alive for from forty-five to sixty minutes, and these seem to me more resistant than the "potato-bacillus" furnished me by Dr. Globig. These long bacilli which I have found so resistant grow somewhat like the various "potato-bacilli." They form a very firm white film on bouillon and nutrient gelatine. This latter medium the colonies gradually liquefy, and are always white, as also is the case in gelatine tube-cultures; but here the liquefaction progresses slowly in the depth, as the growth is typically aërobic. On agar the culture is smooth, yellowish, and not usually spreading. On potato this spreads as a thick, viscid mass of a dingy grayish-yellow color. The average length of the slender bacillus is four to five micromillimetres ($\frac{1}{5000}$ inch), and the ends are rounded except when there are chains (usually containing four individuals). The spores are long-ovoidal and are not at the ends of the bacilli. They often cause a considerable bulging of the wall of the bacillus.

Besides a number of incomplete and preliminary trials, I have carefully conducted fifty-six experiments, at the Carnegie Laboratory and elsewhere, in order to be able to speak with precision. To detail all of these—even in a tabular manner—would show no more than can be learnt from what I have outlined of the process; still I will give a sketch of one of the latter trials as a type of the method employed in all. From a series of tests, colonies of the bacilli described above were found growing on the plates made with the addition of water which had boiled so long as to leave alive none of the other varieties. Then some of these bacilli, from pure cultures of varying ages on different media, and revealing many spores, were added to two litres of impure water having much organic matter in it. The whole was strained through muslin, then tested, and at once agitated and decanted into nine Erlenmeyer flasks, plugged with cotton and sterilized by long exposure to a temperature of 155° C. To the neck of each a thread was attached and then these flasks were all, at the same time, rapidly lowered into a large Arnold steam sterilizer, which, by the combined use of a rose burner and a large Bunsen burner, was maintained at its highest heat. After the introduction of the plugged flasks of cool water into the steamer, it was quickly closed and the time was taken from that moment. By a series of previous tests it had been determined that the micro-organism in question could resist for from thirty-five to sixty minutes at least. So, the flasks were steadily heated for thirty-seven minutes, then one of these was removed so as not to materially affect the heat of the others, of which the last remained at the temperature of 100° C. for one hundred and three minutes in all. In these steaming flasks, the water being at once sampled and added to warm gelatine, and this then poured upon the bottom of glass plates (after Petri's manner), the several thousand germs in each cubic centimetre were found to have diminished in number so that

After boiling for	37	minutes	only	39	were alive.
"	" 48	"	"	23	"

"	" 58	"	"	3	"
"	" 68	"	"	3	"
"	" 72	"	none were alive.		
"	" 79	"	"		"
"	" 89	"	"		"
"	" 103	"	"		"

The flasks were allowed to cool gradually. Then samples were tested, after one, seven, and ten days. In the temperature of the laboratory the water retained its heat so long that the bacteria lost their vitality before it became cool, even in the flask steamed for only thirty-seven minutes. In a sample of the original water reserved for comparison they multiplied to a great extent; yet all the waters were kept under precisely the same conditions, except that the sample of the original had not been exposed to heat.

Professor Anagnostakis, of Athens, refers to passages in Hippocrates and Galen to show that among the ancient Greeks pure boiled water, as also that to which salt had been added and then boiled, was valued for cleansing wounds and in surgical operations. We have since their time advanced in knowledge of the process of nature, yet it is interesting to find the same means recommended in the latest communication of a typically skilful modern surgeon, Professor H. Fritsch, of Breslau, who announces that for the most hazardous and delicate operations, conducted, of course, with careful cleanliness, only a 6 to 1,000 solution of common salt is needed for washing wounds, and for the peritoneum this physiological fluid, when sterilized by heating, is preferable to water made sterile by the usual chemicals, as carbolic acid and corrosive sublimate, so much used nowadays for this purpose.

All surgeons must admit the importance of sterilizing the water used to cleanse the exposed surfaces in, for instance, an abdominal operation, where solutions of antiseptic substances are by some considered objectionable. It seems therefore well to know that all germs in the water used are rendered harmless if it has been boiled for an hour before the operation and then allowed to cool.

In a series of solutions of morphine and other alkaloids, steamed for the same time and then kept closed, I have found that they are now perfectly good after standing for over a year, for no micro-organisms remained alive in these, and no new ones have been allowed to enter. In some of these solutions, moreover, grape-sugar, milk-sugar, and albuminous elements were present in abundance.

Although it is considered that the great majority of the numerous bacteria living in the waters supplied by the average hydrants are quite harmless, still every practical bacteriologist appears averse to drinking-waters which he knows to be teeming with bacteria, and when asked to decide between several given waters, would indicate his preference for one from a pure spring (where these low forms of life are at most only very sparsely present), as against the water from a sluggish river or lake draining a thickly populated region (in which water micro-organisms are exceedingly abundant), even though the two waters appear chemically not unlike.

We have no right to theorize that the presence of numerous saprophytic or other bacteria in the alimentary tract facilitates the digestive processes. Far from it. Their activity is very uncertain and unsafe as compared with that of the normal digestive juices. Whoever has put two equal pieces of meat into two flasks, one with serum with many bacteria, and the other having a digestive solution resembling the secretion of the healthy adult stomach, must have been impressed with the fact that the latter effects solution of the meat in a few hours, while the meat in the bacterial solution may have undergone little change after days and weeks. The bacteria, however, will have increased enormously, and have given off great amounts of foul gases and other noxious products.

Those who are doubtful as to whether boiling does not deprive water of elements necessary to perfect nutrition may be assured that such cooked water is eminently wholesome; indeed, by lessening the amount of oxygen and carbonic acid, the process of heating makes the water less liable to take up lead, lime, and other minerals. The objection that heating "devitalizes" it can, of course, be urged against solid foods as well, and seems to be advanced most by those who criticise in a spirit of controversy. When the "vitality" of hydrant- or well-water means the presence of disease-germs, it seems far from being a recommendation. Among our antipodes, as well as in many model families of our own race, the practice of cooking water is prevalent, and, as far as can be learned, the effects seem distinctly salutary rather than otherwise. The absence of the agreeable taste produced by oxygenation seems the chief objection. This is a considerable one, and can be in part remedied by the introduction of a small proportion of teas or agreeable salts; or air can (in a primitive fashion) be introduced by a bellows in the absence of more elaborate apparatus.

Conclusions.—Unless extraordinarily resistant, water becomes sterilized if it be at or near the boiling temperature for fifteen minutes. If the same degree of heat be maintained for five minutes, all harmful micro-organisms will have been destroyed. Still less time serves to destroy the disease-producing varieties which are recognized as liable to occur in water. Thus merely raising to the boiling-point a clear water containing the micro-organisms of malarial disorders, typhoid, cholera, diphtheria, or of suppurative processes, and allowing it to gradually cool, insures the destruction of these germs. They are also destroyed by keeping the water for from a quarter of an hour to half an hour at a temperature of 70° C.

Occasionally, however, very resistant but harmless bacteria may get into water. The brief heating renders them safe for drinking purposes; but when it is desired to destroy every micro-organism that may be present in a contaminated water, it should be heated for one hour and allowed to cool slowly. Then it may be used for cleansing wounds or for alkaloidal solutions which will keep indefinitely if no germs be introduced after the solution has been heated.

Clinical Department.

COMPOUND BELLADONNA LINIMENT IN ACUTE RHEUMATISM.

By JOHN C. BERRY, M.D.,

KIOTO, JAPAN.

I HAVE recently experienced such gratifying results from the use of chloroform and belladonna in acute rheumatism that I am prompted to call attention to its merits as a local remedy in this disease. Its use may have been observed by others, but I find no reference to it in any of our leading text-books.

For some time past I have used belladonna liniment and chloroform—seven to one—applied on spongio-piline, for lumbago, a note in Squire's "Companion to the British Pharmacopœia," in which the author gives his personal experience with the remedy when suffering from this disease, having first recommended it to my notice. Eades, in his "Therapeutic Handbook," refers to this as a new liniment for the United States Pharmacopœia, and mentions its use for muscular rheumatism.

Our Pharmacopœia does not contain the linimentum belladonnæ comp. It is composed of linimentum belladonnæ, seven parts, and chloroformi belladonnæ, one part—chloroformum belladonnæ being made from powdered belladonna root, twenty, and sufficient chloroform to percolate twenty.

To seven parts of this compound belladonna liniment I add from one to two parts of pure chloroform and apply by sprinkling over spongio piline, wrung out of hot water. This is then firmly pressed on the affected joint for five minutes, and renewed once if necessary, following which the joint is wrapped with hot cotton and recovered with oil-silk and bandage.

The nurse and patient in this case, the latter an intelligent gentleman, were instructed in the use of the remedy, thus preventing any loss of time, an application being made as soon as a joint became invaded by the disease. The pain was usually controlled in about fifteen minutes. In case of one joint—a shoulder, where a relapse occurred

—a second application was required, resulting in a blister and immediate cessation of pain.

Thus, though it is usual in such disease to have several joints involved at once, the pain in each lasting from two to four days, there was no time in this illness when a new joint became involved, before the pain in the one last attacked was under control, though the number affected was twelve.

Equally satisfactory was the influence of the remedy in preventing large accumulations of fluid around the joints, and in promoting absorption, none of the joints affected long remaining stiff and painful on motion.

I should perhaps add that over the superficial joints the use of the belladonna was followed by painting with a ten per cent. solution of cocaine in oil; but from the effect of the belladonna on the larger joints I judge the use of the cocaine to have been unnecessary for the control of the more severe pain, though the patient says there was more complete freedom from pain on motion in joints thus treated than in those in joints to which cocaine was not applied.

The advantages of the compound belladonna liniment and chloroform as a topical application are, therefore: 1, It is strongly anodyne; 2, it is a powerful stimulant and revulsive. It therefore performs the work of both anodyne and blister.

No constitutional effects from belladonna were produced during the several applications.

I should add that the general treatment was with laxatives, salicylates, and alkalies, followed by iron, quinine, and electricity.

I shall be interested to learn if the treatment with belladonna and chloroform is followed by such immediate relief in younger patients, my case being nearly fifty-two years of age. The attack, however, was severe.

A CASE OF SOMNOLENCE.

By L. N. SHARP, M.D.,

MINNEAPOLIS, MINN.

On March 3d last I was asked to see an old lady, eighty-two years of age, who had enjoyed good health and carried a considerable amount of flesh. She had an attack, about ten days before, of what I considered the passage of a gall-stone, during which she was cared for by another physician.

When I first saw her she was comfortable, lying in bed, pulse 90, tongue clean, and temperature normal. The following day when I made my visit to her she was sleeping, and as this was quite late in the day, and she had slept all the time since I had seen her the day before, I feared she had been taking some narcotic, but of this there was no other evidence, save sleep. I saw her day after day for three weeks, during which time she continued to sleep day and night, constantly, only when awakened to take some liquid nourishment and then she would, perhaps, partly answer a question and fall into a sweet and apparently pleasant sleep. No abnormal condition appeared present otherwise. When the second week came on I thought she could be aroused more readily, and at the end of the third week she could be kept awake by talking with her for perhaps an hour at a time, in the afternoon only. From this time on she gradually slept less and soon gained strength, her appetite returned, and she was, in a short time, around the house as usual.

During this time of sleep the pulse and temperature remained normal. The urine was voided part of the time without her knowledge, but generally she manifested uneasiness, and her attendants would use the bed-pan. The bowels did not move till about the close of the third week, and then the passage was not formed. She had been freely purged before I saw her. When she came out of her sleep she was impressed that she was in a hospital, and could not reconcile her surroundings with what she was accustomed to, while she had occupied the room in which she had slept for a long time in the house of her daughter. No other delusion or any indication of cerebral trouble was manifest.

Progress of Medical Science.

A New Method of Artificial Respiration.—Dr. Andrew H. Smith, of this city, writing in the *Virginia Medical Monthly* for April, 1890, describes an improved method of performing artificial respiration. Two persons are required. The patient lying on the back, and, if possible, placed upon a table, one operaror at the head takes a hand in each of his and draws the arms directly upward, with a slow and steady pull, continuing the traction until the maximum of thoracic distention is obtained, which will require about three seconds. This accomplished, the traction is relaxed, without, however, attempting to press the arms against the sides. At this moment the other operator, who is kneeling or standing by the side of the patient, presses with both hands forcibly upon the chest in a direction backward and toward the median line, so as to diminish both the depth and the breadth of the lower half of the thorax. This pressure, like the traction, is to be made slowly and steadily, and should be continued until the maximum expiratory result is attained, say two seconds. The pressure is then relaxed, and the traction on the arms follows again immediately. In this way about twelve respiratory movements per minute will be accomplished, under conditions giving the largest excursion of the chest-walls attainable by manual procedure. It will be seen that this is a combination of a part of Sylvester's method with the method of Howard. Sylvester's method is defective, in that it does not provide for efficient compression of the thorax; the position of the operator at the head of the patient making such compression extremely difficult. Howard's plan, on the other hand, does not provide for any expansion of the chest beyond the cadaveric position, and is, upon the whole, much less effective than Sylvesters. A combination of the two, carried out by two person's, secures a very considerable approach to the results of natural respiration, the action of the diaphragm alone being unrepresented. Another very great advantage is the division of labor—either of the other methods being exceedingly fatiguing to the operator.

Coffee Inebriety.—Dr. Mendel, of Berlin, has lately published a clinical study of this neurosis, his observations being made upon the women of the working population in and about Essen. He found large numbers of women who consumed over a pound of coffee in a week, and some men drank considerably more, besides beer and wine. The leading symptoms were profound depression of spirits, and frequent headaches, with imsomnia. A strong dose of coffee would relieve this, for a time, then it would return. The muscles would become weak and trembling, and the hands would tremble when at rest. An increasing aversion to labor and any steady work was noticeable. The heart's action was rapid and irregular and palpitations and a heavy feeling in the precordial region were present. Dyspepsia of an extreme nervous type was also present. Acute rosacea was common in these cases. These symptoms constantly grow worse, and are only relieved by large quantities of coffee, generally of the infusion. In some cases the tincture was used. The victims suffer so seriously that they dare not abandon it for fear of death. Where brandy is taken only temporary relief follows. The face becomes sallow, and the hands and feet cold, and an expression of dread and agony settles over the countenance, only relieved by using strong doses of coffee. In all these cases, acute inflammations are likely to appear any time. An injury of any part of the body is the starting-point for inflammations of an erysipelatous character. Melancholy and hysteria are present in all cases. Coffee inebriates are more common

among the neurasthenics, and are more concealed because the effects of excessive doses of coffee are obscure and largely unknown. Many opium and alcoholic cases have an early history of excessive use of coffee, and are always more degenerate and difficult to treat. A very wide field for future study opens up in this direction.—*The Quarterly Journal of Inebriety*, April, 1890.

The Surgery of the Abdomen, with Some of its Responsibilities.—Dr. Thomas H. Manley, of New York, read a paper with this title before the Section on Neurology and Medical Jurisprudence at the Nashville meeting of the American Medical Association. Abdominal surgery, he said, was until recently an unexplored field. Since Lister's time, however, eminent surgeons and those of mediocre prominence have not scrupled to employ the scalpel very freely, but with very unfavorable results. A reaction has set in, and conservatism in dealing with abdominal injuries is now on the ascendant. In severe ventral traumatisms it is a concern of serious importance whether the case be left to nature's unaided powers, or whether, bearing in mind the obscure nature of all abdominal lesions, one is not justified in making an exploratory incision. From statistics lately collected it is clearly manifest that, in cases of injury due to gunshot and stab wounds of the intestine, the percentage of recoveries is far larger where the *expectant* plan of treatment is resorted to than where the operative procedure is carried out. When we review the processes by which the full functional activity of the injured parts is restored by the *vis medicatrix naturæ*, we shall not be surprised at the results due to the expectant or non-interfering plan. Shock results after injury to the abdominal contents; hemorrhage follows, after the absorption of which inflammation sets in. If the intestinal wound be small, scarcely any of its contents escapes. In gunshot wounds the valvular-like opening is immediately closed by the contraction of the mucous coat and peristalsis is temporarily paralyzed. If the patient survive, inflammation ensues, which is limited in extent. It is necessary as a factor of repair. Laparotomy must be regarded under all circumstances as an operation of the greatest magnitude, notwithstanding the strictest antiseptic precautions. The pump-like action of the diaphragm seriously interferes with primary union in man, and the median incision leaves a tendency to hernia. Permanent recovery has ensued in only one case, where resection of the intestine was resorted to for strangulated hernia in the male; and this was in the practice of Dr. Perwit, of St. Louis. Though anæsthesia and antiseptics have revolutionized surgery, it seems that our progress in dealing with intestinal lesions is not much further advanced than it was a century ago; and this is owing to doubt regarding the nature and extent of these lesions.

Pilocarpine in Chronic Articular Rheumatism.—Dr. Charles Hochalt reports the following case in the *Orvosi Hetilap*, April 27, 1890. Mary Molnar, aged forty-five, cook, was taken sick three years ago with acute articular rheumatism, having previously enjoyed perfect health. She recovered from this attack at the end of four weeks, but there remained an insufficiency of the mitral valve. After the lapse of a year a second attack of rheumatism came on, which left the joints in a painful condition, and finally, the latter became shrunken and entirely motionless. On admission into the hospital the joints presented the following appearance: Elbow-joints anchylosed at right angles, and no active or passive motion detectable. The wrists possess only a trace of passive mobility, while the finger-joints are perfectly stiff and flexed. Both knee-joints are swollen and bent, but capable of passive motion to an angle of sixty degrees. The toes are flexed and motionless. The only joints, however, which show a perceptible change of structure are the elbows, which are enlarged and crepitant. Muriate of pilocarpine in two per cent. solution was used hypodermically at intervals of three or four days, in doses at first of 1 ctgm., later 2 ctgm. The result was most gratifying. During the first few days a change for the better had taken place, and after the tenth day of treatment the patient was able to rise from bed and walk. After the ninth injection the stiffness of the wrists and fingers was relieved, and patient was able to eat and to button her dress. The elbow-joints failed to respond to treatment. The medicine produced copious sweating and salivation, and no untoward action on the heart was observed. The author would recommend further trial of the drug in chronic articular rheumatism.

Electrolysis in the Treatment of Diseases of the Skin.—The following are the conclusions arrived at by Dr. Leviseur, of this city, in an interesting article in the *Monatshefte fur Praktische Dermatologie*, No. 7, 1890: 1. Electrolysis does excellent service in cases of cosmetic operations upon the face. 2. The monopolar method with the negative pole is the easiest of performance and gives the best results. 3. The performance of electrolytic operations should never be entrusted to lay hands, and even the physician should not attempt work of this kind unless he has good instruments and necessary apparatus. 4. In the treatment of malignant neoplasms or those of rapid growth, electrolysis is not powerful enough and is too slow, yet the reports of certain operators in this field, who have been working with improved instruments and after a perfected method, give encouragement for further trials in such cases.

Sudden Removal of Nerve-pressure as a Cause of Pain.—In a paper read before the Mississippi Valley Medical Association (*Lancet*, April 12, 1890), Dr. Edward F. Wells reported two cases in which excruciating pain in the legs followed childbirth. In each instance there had been considerable œdema of the leg, and the pains were found to follow the subsidence of this œdema, and to be greatly relieved by the application of a tight bandage. Dr. Wells believed the pain to have been caused by the rapid subsidence of the œdema and the consequent relaxation of the long-continued pressure upon the nerves of the parts. He cites in support of this view the well-known fact that pain follows the sudden removal of pressure in other parts, as upon the emptying of an over-distended bladder, the unwinding of a constricting bandage, etc. He suggests, furthermore, that the pains experienced by chronic rheumatics and some others before storms and other violent and sudden meteorological changes may be due to rapid withdrawal of the atmospheric pressure exerted upon the body and its contained nerves.

Testing a Suture of the Gastric Wall.—Dr. Meinhard Schmidt, of Cuxhaven, writes in the *Centralblatt für Chirurgie*, No. 14, 1890, that, having lost a patient upon whom he had performed resection of the pylorus, by reason of the escape of liquid matter through the line of sutures, he set about to devise some means of determining whether the sutures were tight or not before closing the abdominal wall. He had inserted the sutures with great care and believed that they were sufficient to hold the edges of the wound in close apposition, but after the death of the patient examination showed a slight separation at one point. He suggests that, in future, a test of the closeness of the sutures be made by introducing a sound attached to a rubber bulb, and filling the stomach with air, the duodenum being compressed in order to prevent the escape of air in that direction. If no air escape it may be assumed that the edges of the wound are in close apposition, and then the operation may be completed.

Chlorodyne Poisoning through the Mother's Milk.—A case is reported in the *Australasian Medical Gazette* of a woman who had recently given birth to twins, and was suckling them both. One evening she took a dose of chlorodyne for the relief of pain, and soon after taking the drug suckled the infants. The children were found the following morning profoundly narcotized, and died before evening.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 14, 1890.

THE EDUCATION OF THE EXTERNAL PTERYGOIDS IN STUTTERERS.

THERE are very few things in this age of education which man has not tried to educate. From the trained pig to the moral sense the art of pedagogy has fruitfully applied its resources. The special education of the external pterygoid muscles, however, strikes us as possessing some novelty. This measure has been recently advocated in the *Monthly Homœopathic Review* by Dr. Edward Blake, who thinks it an essential measure in the treatment of "stammering." A careful perusal of Dr. Blake's article leads us to think that, while his treatment may have some practical value, its author possesses a profound ignorance of the general subject upon which he writes. Such a mental condition we have observed before, however, in contributors to current literature, and we shall not let it produce an unwarranted bias against the pedagogic treatment of the external pterygoids, of whose existence, origin, insertion, and functions we retain pleasant reminiscences gained during student days.

Dr. Blake does not mean "stammering," but "stuttering," when he writes about the pterygoids. Stammering is an imperfect articulation of speech sounds, of which lisping, lambdacism, rhotacism, etc., are illustrations; while stuttering is a spasmodic defect in speech of functional origin. Dr. Blake is very much mistaken when he says they are the same thing.

Stuttering being a functional spasmodic disorder, some what of the nature of a habit-chorea, it is not surprising that in these days it should be looked upon as a reflex neurosis, and such, in a measure, is our author's view. Some stutterers, we are told, are unable to protrude the lower jaw owing to defective innervation of the external pterygoids. Charles Kingsley is said to be a case of this kind. These muscles are also the most important agents in grinding, and, when weak, food cannot be perfectly triturated. In consequence the nervous system suffers severely from innutrition! Hence, educate the pterygoids to grind better, and protrude the lower jaw in obedience to expressional or masticatory necessities.

Dr. Blake's treatment is better than his theory, for it includes a sop to modern rhinology, and a proper deference to what sense and experience have shown regarding the education of the power of breathing rightly.

The following is an interesting and useful schedule of the methods applied in one case:

1st. The left hypertrophic rhinitis was removed by means of the electro-cautery.

2d. The peri-Eustachian adenoids were scraped away.

3d. External pterygoid muscles were educated in two ways. (*a*) By direct electric stimulation; (*b*) by appropriate active, passive, and resistant movements. First an electrode was passed up behind the soft palate to the inner aspect of the lower fibres of the external pterygoid muscle, just in front of the Eustachian orifice. A well-wetted disk was then applied over the malar bone of the corresponding side, and a combined current consisting of faradic—gentle secondary, voltaic—1 milliampère gradually raised to 2, using commutator to prevent skin injury, was employed during two minutes at a sitting.

4th. A trained masseuse applied electro-massage to the poorly developed muscles of respiration. *A*, Effleurage slow; *B*, pétrissage firm; *C*, tapottement smart.

5th. With the legs and pelvis supported on a table, the trunk unsupported, the attendant aided the patient in going through all the spinal movements, especially using the dorsal portion of the spine to increase its flexibility—thus adding to the mobility of the ribs at the same time.

6th. The lung capacity was greatly increased by quickly expelling, as far as possible, the residual air by forced expiration through the nearly closed mouth, patient standing with hands grasping some suitable support. Next the head is raised, the shoulders are thrown back, and a very long, very slow inspiration taken through the nose; this ought to take fifty seconds. The air is retained as long as possible, and then suddenly delivered through the mouth and nose. This raised her chest measurement from twenty-seven to twenty-nine inches by the end of January.

7th. She reads very slowly in French, uttering every syllable with equal emphasis, as if she were taking a lesson in Hindustani. French is selected because it is the language *par excellence* in uttering which the use of the lower lip cannot be avoided."

Finally, the state of the skin and the diathesis are properly attended to.

COLLEGIATE EDUCATION AND THE MEDICAL PROFESSION.

THE question of a college education in its relation to business occupations and to the liberal professions is again exciting deep interest. The discussions, at least, show a wide-spread feeling that there is something wrong in the present methods and tendencies of some of our colleges.

The doctor has a special interest in this subject, for these methods, as pursued in some quarters, are tending more and more to take away the possibility of any large proportion of young men going through college before they study medicine.

In a recent address delivered by Dr. D. B. St. J. Roosa, before the Yale Association of Fairfield County, this matter was most forcibly presented, and the difficulties which have been raised by the modern collegiate curriculum logically set forth. There is no combating Dr. Roosa's conclusions, which are substantially in harmony with what we have before presented to readers of the MEDICAL RECORD.

It is desirable for those who are to follow a liberal profession to have a liberal education. It not only broadens the mind, trains the faculties, but gives one larger capacities for enjoying life. Admitting this, however, it is equally true that few prospective doctors can afford to go to a college from which they can only graduate at the age of twenty-two or twenty-three. For they cannot then complete their medical education and get to practice before they are twenty-seven or eight; and they are not earning a living until they are thirty.

It seems to be agreed that a sufficiently liberal education ought to be acquired by the age of twenty, or at the end of the sophomore year in a university like Harvard. At this time special lines of work should be begun, bearing reference to their future calling in life. In other words, as Dr. Roosa puts it, college education should end at twenty, and university education begin at that time. The system which has gradually been evolved at Harvard is utterly unsuited to the great majority of American students. "It is neither fish, flesh, fowl, nor good red-herring," says our lecturer most truthfully; it is too much for a college education, and not enough for a university education.

What shall be done then? We can let our large so-called universities settle it among themselves. There are enough rich people in the country to no doubt support such institutions, if they do not wish to change. But, meanwhile, young men who want to study medicine, or law, or engineering, or go into business, and also go through college, should attend those institutions which are in fact colleges, and which get them through by the time they are twenty years of age.

As a matter of fact this is being done. There are very few Harvard graduates in the Harvard Medical School, whereas in Dartmouth Medical College, for example, nearly one-third of the students are graduates of the Academic Department. We advise young men to get a good, sound, liberal education at a small and a genuine classical college. Many can finish this even before they are twenty. Then they are none too old to start in with their professional studies.

RECENT MEDICAL LEGISLATION FOR THE STATE OF NEW YORK.

The last session of our State Legislature was little less than disastrous so far as the interests of better medical education are concerned. In the first place, a law was passed permitting any person who wishes to matriculate as a medical student, to pass his preliminary examination at any time during his first three years of study. This practically nullifies the law, and permits any man to enter upon the study of medicine without a test of his educational fitness. The law, as it stood before, had some defects which could have been easily remedied. The present amendment totally destroys its force. It was secured, as is well known, through the political influence of the managers of certain medical colleges of this city, and against the wishes and judgment of the medical profession of the State as a whole.

The second piece of pernicious legislation was the enactment of a law establishing three Boards of Medical Examiners. This was done also despite the protests of the vast majority of the medical profession, including even many prominent homœopaths. Several influential daily papers, among them the *Sun*, the *Times*, and *Tribune*, either opposed the law or printed strong and candid statements of the reasons why it should not be enacted.

The final passage of the act is unfortunate and humiliating, for it shows again how little weight the opinions of physicians upon public matters have in political circles.

We trust that next winter there will be concerted action to secure the repeal of the triple board law. Our State and local societies ought to unite vigorously in this matter.

A law was passed providing that physicians who come from another State must pass a qualifying examination before beginning to practise here. This law is a wise and proper one.

News of the Week.

The St. Louis Academy of Medicine sent delegates to the recent meeting of the Missouri State Medical Society, at Excelsior Springs, but they were not recognized, and the Academy feels hurt at the action of the State Society, but it is not known what will be done in regard to it.

A Florida Sanitarium.—A Philadelphia syndicate has purchased a large tract of land on the Gulf coast of Florida, and proposes to establish a sanitarium there. Several physicians of that city are interested in the project.

Alleged Abortionists in St. Louis.—A sensational paper in St. Louis has recently been amusing its readers with columns of accounts of alleged physicians who make their living by fœticide. It asserts that over fifty out of less than seven hundred physicians in that city are engaged regularly in such practice, and that most of the others commit the crime occasionally in consideration of a large fee.

Dr. William Baldwin Linsly, of New York City, died at Pawling, N. Y., June 10th, of heart-failure, after a long struggle with intermittent fever. He was born in this city fifty years ago and was the son of the late Dr. Jared Linsly. He graduated from the New York College of Physicians and Surgeons. He went to the front as surgeon in 1862 and served in the various hospitals throughout the war.

Mississippi Valley Medical Association.—The next annual meeting of this Association will be held at Louisville, Ky., October 8, 1890. A large attendance is expected, and a good time socially and scientifically. The profession of the Mississippi Valley is invited to come and bring their wives, as the ladies always have a good time in Kentucky. Send titles of papers to the Secretary, Dr. E. S. McKee, 57 West Seventh Street, Cincinnati, O., who would also be glad to receive reprints or copies of all papers read at the last meeting, to make the collection as complete as possible.

A Case of Hydrophobia was recently brought to this city and taken to Bellevue Hospital, where the patient died. The victim was a middle-aged man who was bitten by a dog about a month ago. Autopsy has confirmed the diagnosis so far as it could do so, but test-inoculations of rabbits will be made.

Drugs of Uncertain Strength.—Dr. Willis G. Tucker, the analyst of the State Board of Health, has examined sixty-eight samples of drugs collected in May, in Poughkeepsie, Newburg, Rhinebeck, Mattewan, and Fishkill-on-the-Hudson, and of this number thirty-three were deficient in quality, being either of inferior or excessive strength, or articles wrongly sold.

Dr. Edward J. Mealia died on June 5th, at his home in Brooklyn, a victim of the after-effects of an attack of the grip. He was thirty-one years of age, and a graduate from St. Francis Xavier's College, New York. He was also in the Class of '83 in the College of Physicians and Surgeons.

The Fifty-eighth Annual Meeting of the British Medical Association will be held at Birmingham, on Tuesday, Wednesday, Thursday, and Friday, July 29. 30, 31, and August 1, 1890. *President*, C. G. Wheelhouse, F.R.C.S.; *President-elect*, Willoughby Francis Wade, B.A., M.B. An Address in Medicine will be delivered by Sir B. Walter Foster, M.D., M.P.; an Address in Surgery will be delivered by Lawson Tait, F.R.C.S.; an Address in Therapeutics will be delivered by William Henry Broadbent, M.D.

The St. Louis Medical Colleges seem to be prospering. The Marion-Sims College will soon erect a building, the Beaumont Medical College has a building already under way; the College of Physicians and Surgeons has bought a lot and will soon begin to build.

Death of Dr. Charles H. Wilkin.—We regret to announce the death, on June 6th, of another brilliant and promising member of our profession, Dr. Charles H. Wilkin. Strangely enough his death, we are informed, was the result of an appendicitis, the disease which has carried off so many physicians of this city. Dr. Wilkin graduated from the College of Physicians and Surgeons in 1878, and at the time of his death had acquired a large practice.

New Medical College at Chattanooga, Tenn.—The University of the South, Seewanee, Tenn., will establish, in October, at Chattanooga a department of medicine. The outline of the medical department indicates a medical school of the highest character, strict preliminary examinations by the college faculty being held prior to admission, and three full winter courses of lectures being necessarily attended before graduation.

Legacies to the Hospitals of Philadelphia.—By the will of the late George S. Pepper, the following bequests have been made: To the University of Pennsylvania, $60,000, for the endowment of a professorship; Hospital of the University of Pennsylvania, $50,000; Presbyterian Hospital, $50,500; Hospital of the Protestant Episcopal Church, $50,000; Orthopædic Hospital, $25,000; Pennsylvania Hospital, $50,000; Hospital of the Jefferson Medical University, $50,000; Charity Hospital, $25,000; St. Joseph's Hospital, $25,000; Children's Hospital, $25,000; Wells Hospital, $10,000; St. Christopher's Hospital for Children, $25,000; Hospital and Dispensary of St. Clement's Church, $10,000; Children's Hospital, Country Branch, $10,000; Maternity Hospital, $25,000; Northern Dispensary, Southern Dispensary, Philadelphia Dispensary, Howard Dispensary, each $5,000.

The Adirondack Park Association has been permanently organized for the purpose of preserving the "north woods" from further depredations. Dr. Alfred L. Loomis has been elected president, and Dr. Martin Burke, secretary.

The New Hampshire Medical Society will hold its ninety-ninth annual meeting in Concord on Monday and Tuesday, June 16th and 17th.

Another Medical School.—The Nebraska Christian University was established, and opened its first term in Lincoln last autumn. This year it has added a medical school, which will commence its sessions in the coming September.

The Connecticut Medical Society held its ninety-eighth annual meeting in New Haven in the latter part of May. The following officers were elected: *President*, Dr. M. Storrs, of Hartford; *Vice-President*, Dr. C. A. Lindsley, of New Haven; *Treasurer*, Dr. W. W. Knight, of Hartford; *Secretary*, Dr. W. E. Norden.

Boston's Streets.—A petition, signed by over one hundred physicians of Boston, was recently submitted to the city council, protesting against the filthy condition of the streets, and urging immediate remedy before the advent of hot weather.

The Philadelphia Lying-in Charity.—There is some trouble in this institution concerning the appointment of the physician in charge. This is one of the oldest and best-known lying-in hospitals in this country, having been established by Dr. Joseph Warrington in 1828, and incorporated in 1832. The present trouble is the outcome of a long-continued epidemic of puerperal fever which developed in the hospital, and the responsibility for which the resident physician and the physician in charge mutually throw upon each other.

The Kentucky State Dental Association met in Louisville the first week in June. About seventy-five members took part in the meeting.

The Cook County (Ill.) Hospital and the Coroners.—There is loud complaint in the coroner's office, in Chicago, of the actions of those in charge at the county hospital. It is claimed that there is often delay in reporting deaths to the proper authorities, and it is not infrequent, when they are reported, that necessary details are omitted and inquests delayed.

Emergency Hospitals in Chicago.—Steps have been taken in Chicago for the erection and equipment of emergency hospitals in preparation for the world's fair.

The Ulster County (N. Y.) Medical Society held its annual meeting in Kingston on June 3d. The following officers were elected for the ensuing year: *President*, Dr. C. L. Dodge; *Vice-President*, Dr. E. H. Loughran; *Treasurer*, Dr. Jacob Chambers; *Corresponding and Recording Secretary*, Dr. A. A. Stern; *Censors*, Drs. A. H. Mambert, C. W. Crispell, A. H. Palmer, Josiah Hasbrouck, Jr., and Patrick Hayden.

An Anti-Premature Burial Society.—It is said that a number of physicians and laymen are about to organize a society having for its object the prevention of premature burial, an occurrence which the promoters of the organization believe to be more common than is generally supposed.

Physicians Going to Europe.—The passenger lists of all the out-going steamers contain many names of physicians who are going to Europe for the summer, the Berlin Congress being in many cases merely an excuse for the trip.

The Annual Meeting of the Medical Association of Ontario was held in Toronto on June 11th and 12th. Several physicians from this country were present and read papers. The association was founded about ten years ago, and now numbers about six hundred members.

The Memphis City Hospital.—The faculty of the Memphis Hospital Medical College recently submitted a petition to the city council praying that the entire medical management and control of the city hospital be placed in their hands. The council did not seem to appreciate the advantages of the proposition, and refused it by a vote of seven to one.

The Essex District Medical Society and the Census.—A special meeting of this society was held at Newark, N. J., to discuss the circular recently distributed by Dr. Billings. After some discussion the following resolution was unanimously adopted:

Resolved, That neither as contributing to truly scientific and accurate statistical investigation, nor in conformity with the honest ethics of our profession, can we consider it necessary or proper to comply with the request sent to the physicians of the United States by the Census office.

An Unjust Discrimination.—The medical examining board of Washington consists of nine members, appointed by the Governor, three only of whom are regular physicians. At the recent annual meeting of the State Medical Association, held at Spokane Falls, a committee was appointed to draft a communication addressed to Governor Ferry. In this protest it is stated that over seven hundred of the eight hundred practising physicians in the State are regular, yet the profession is in a minority on the board and they pray that a redistribution may be made whereby they may have a pro rata representation in that body.

The Medical Examiners Bill, which passed the New York State Legislature a short time ago, was signed by the Governor on June 6th. The act provides that there shall be three separate boards, one representing the Medical Society of the State of New York, one the Homœopathic Medical Society, and one the Eclectic Medical Society. Each board shall consist of seven members, each of whom is to serve for a term of three years. The power of appointment rests with the board of regents of the University of the State of New York, the appointments however being made from the lists of nominees submitted by each of the three medical societies named, the selection of these nominees being made by majority vote at the annual meetings of the societies. Every person appointed to serve on these boards shall receive a certificate of appointment, and within thirty days after receiving such certificate shall take the required oath. The boards are authorized to take testimony concerning all matters within their jurisdiction, and the presiding officer may issue subpœnas and administer oaths to witnesses. At the first meeting of each board a president and secretary shall be elected. For the purpose of examining applicants for license, each of the boards shall hold one or more meetings in each year, due notice of which shall be made public, at such times and places as may be determined by the board of regents. Each examination shall be under the supervision of an examiner appointed by the board of regents, and who shall not be a member of any board of medical examiners. At the meetings of the board a majority of the members shall constitute a quorum, but the examination may be conducted by a committee of one or more of the members of the board. The several boards of examiners shall submit to the board of regents lists of examination questions in anatomy, physiology, hygiene, chemistry, surgery, obstetrics, pathology, diagnosis, and therapeutics, including practice and materia medica. From this list of questions the board of regents shall select the questions for each examination, and present the same to the candidates by an examiner appointed therefor by the board of regents, "and such questions for each examination shall be so selected as to require the same standard of excellence from all candidates, except that in the department of therapeutics, practice, and materia medica the questions shall be in harmony with the tenets of the school selected by the candidate.

"The examination shall be conducted in writing, and at its close the examiner appointed by the board of regents having supervision thereof, shall forthwith deliver to the board of medical examiners having charge of such examination, or to their duly authorized committee, the questions submitted to, and the answers of, each applicant, and such board of medical examiners, without unnecessary delay, shall transmit to the regents of the university an official report, signed by the president, secretary, and each acting member of said board of examiners, stating the examination average of each candidate in each branch, the general average, and the result of the examination, whether successful or unsuccessful. Said report shall embrace all the examination papers, questions, and answers thereto. All the examination papers so returned shall be kept for reference and inspection among the public records of the university.

"On receiving from either of said boards of medical examiners an official report of the examination of any applicant for license, the said regents shall issue to every applicant who shall have been returned as having successfully passed said examination, and who shall, in their judgment, be duly qualified therefor, a license to practise medicine and surgery in the State of New York. Every license to practise medicine or surgery issued pursuant to the provisions of this act, shall be subscribed by the chancellor and the secretary of the University of the State of New York, by each medical examiner who reported the licentiate as having successfully passed said examinations, and also by those of the regents who examined and approved the credentials of said licentiate upon the application for examination. It shall also have affixed to it, by the person authorized to affix the same, the seal of the university.

"Nothing in this act shall be construed to interfere with or punish commissioned medical officers serving in the Army or Navy of the United States, or in the United States Marine Hospital Service while so commissioned; or anyone while actually serving as a member of the resident medical staff of any legally incorporated hospital; or any legally qualified and registered dentist, exclusively engaged in practising the art of dentistry; or interfere with manufacturers of artificial eyes, limbs, or orthopedical instruments or trusses of any kind from fitting such instruments on persons in need thereof; or any lawfully qualified physicians and surgeons residing in other States or countries, meeting registered physicians and surgeons of this State in consultation, or any physician or surgeon residing on the border of a neighboring State, and duly authorized under the laws thereof to practise medicine or surgery therein, whose practice extends into the limits of this State; providing that such practitioners shall not open an office or appoint a place to meet patients or receive calls within the limits of the State of New York; or physicians duly registered in one county of this State called to attend isolated cases in another county, but not residing or habitually practising therein."

Society Reports.

American Medical Association.

FORTY-FIRST ANNUAL MEETING.

Held at Nashville, Tenn., May 20, 21, 22, and 23, 1890.

OBSTETRIC SECTION.

(Continued from page 628.)

THIRD DAY, THURSDAY, MAY 22D.

Intra-ligamentary or Embedded Cysts. — DR. WATHEN, of Louisville, read a paper on this subject. After briefly describing the anatomy of the broad ligaments, the parovarium, and other fœtal tubular relics, illustrated by well-executed drawings, he said :

Cysts of the broad ligament are extra-peritoneal, and may be benign and simple, as in the so-called broad ligament cysts, or quasi-malignant, as in the intra-ligamentary, sessile, or embedded cysts. He begged to call attention especially to the latter, as the literature upon this subject is comparatively modern and not extensive. These cysts may appear to be very simple things, but they are often on the verge of malignancy and are frequently infected with papillary ingrowths. They may be divided into unilocular, papillomatous, and multilocular papillomatous cysts. In the former, while the liquid is usually limpid, it is often so poisonous that it may cause rapid malignant degeneration of the peritoneum.

The unilocular cyst is probably from broken vertical tubes of the parovarium, and is more loosely connected by a connective tissue to the broad ligament than the multilocular cyst ; it has less intimate vascular connection, is more encapsulated, and is more easily removed by enucleation. It probably never becomes blended with the fibres of the uterus or bladder by continuity of tissue.

The multilocular cyst has a few daughter cysts, distended by a clear, limpid fluid, with exuberant and firm papillomatous growths.

Its firm union and abundant vascular connection with its peritoneal and fibrous capsule, and its tendency to fuse itself to the muscular tissue of the uterus, bladder, and other sub-peritoneal pelvic structures may make its removal one of the most difficult and dangerous operations in abdominal surgery. Its origin is not settled, but as papillary ingrowths are essential features of fœtal tubular relics it is generally taught that it arises from the tubules of the parovarium. I am, however, inclined to adopt the theory of Doran, that this form of embedded cyst has its origin in stray fœtal relics which exist in the hilum of the ovary. I cannot believe that this cyst arises from follicular degeneration of supplemental ovarian tissue, or accessory ovaries, for papillomatous ingrowths are not found except in fœtal tubular relics, and in the hilum of the ovary relics of the Wolfian body exist in abundance. The walls of this cyst are usually thin, but very great development of fusiform muscular cells may make it at some parts one-half inch in thickness. The liquid is generally limpid, but may be of all shades of consistency and color. It is not probable that this cyst can be diagnosticated by a chemical and microscopical examination of its contents, as claimed by Koeberlé ; nor do I believe it is possible to make a diagnosis until the abdomen has been opened, and even then it is not always an easy matter to do so. It may be confounded in its stages with other pathological conditions. Mr. Tait, in speaking of the pathology of these tumors, says : " The cells are irregular in size, and often in form, often ciliated, but incompletely so ; they evince an immunity of growth which I hold to be the only characteristic of malignant disease. When the tumors have reached large size this epithelial proliferation becomes dendritic and papillomatous, and some of these simple-looking tumors are among the most malignant I have met with." He removed a simple-looking embedded cyst from a young girl where no dendritic or papillomatous growths were visible. She had cancer in six weeks, and died in three months with cancerous involvement of all the important pelvic and abdominal organs. This special instance does not stand alone in his experience. The liquid of the cyst is often so acrid and poisonous to the peritoneum as to positively contraindicate any form of tapping or aspiration through the abdomen, and the only treatment that is justifiable is laparotomy and careful enucleation of the cyst from its peritoneal and fibrous covering. But this is not always an easy matter, and the enucleation is sometimes so difficult and attended with such profuse hemorrhage as to cause the woman to die on the operating table. The bladder may be opened in an effort to separate the cyst when there is continuity of structure. This misfortune has occurred twice in the experience of Goodell, who has probably had more experience in the removal of embedded cysts than any man in this country. Or the cyst may have so buried itself in the pelvis as to make it impossible to entirely remove it without endangering the large vessels deep in the pelvis.

No one should attempt to shell out the embedded cyst until he understands the anatomical relations it sustains to its investing membrane and the organs and structures of the pelvis, otherwise he will not do good surgery, may fail to remove a cyst that could be easily enucleated, and may also cause the death of the woman. The cyst-walls are often so rotten as to rupture with but little careless handling, and allow the poisonous contents to enter and infect the peritoneum. For this reason it is probably better to remove the fluid with an aspirator before attempting enucleation, and then close the little opening with catch forceps. The investing membrane should be opened at the most favorable point, and with well-trained fingers one should carefully work from that point, otherwise he may lose his bearings, do a bad operation, and fail to remove the cyst. When the cyst is removed the empty capsule, if small at its base, may be ligated low down and cut away ; but with a thick, broad base, where there is oozing, the edges of the capsule should be drawn together by a purse-string suture stitched to the bottom of the abdominal wound and a drainage-tube introduced.

Severe Vomiting of Pregnancy.—DR. E. W. MITCHELL, of Cincinnati, made a report of two cases on this subject. Both were II-para, both had obstinate vomiting in first pregnancy, with much prostration. This had ceased spontaneously at three and one-half months. Both had sustained a laceration of the cervix with some cicatricial deposit in the rent.

Case I. had an attack of puerperal fever after the first labor, which left her in an invalid state from which she had not fully recovered when she became a second time pregnant, six years later. Vomiting in the pregnancy was so extreme, and loss of strength so rapid, that, after consultation, abortion was induced by the use of the faradic current. Patient made a prompt recovery.

Case II. became pregnant seven months after the birth of the first child and began vomiting at third or fourth week. The emesis gradually increased in severity until it became almost incessant, even preventing sleep at night. Rectal feeding was only partially successful, the injections being only retained when the patient was under the influence of opium. No remedy stopped the vomiting except opium by suppository or morphia hypodermically. Rectal injections of chloral and bromide and nitrate of silver to os were without benefit. Copeman's method of dilating cervix by introducing the index-finger was successful in stopping the emesis, but an abortion followed seven days later. Patient made a good recovery.

Uterus Bilocularis was the subject of a paper by DR. L. H. DUNNING, of Indianapolis. He related an interesting case which had occurred in his practice and referred to a former paper of his on this same subject.

The paper was discussed by DR. A. F. CURRIER, of

New York, who did not think that we could certainly say whether we had a uterus bilocularis or not unless we had the uterus before us.

Fistulous Escapes of Ligatures after Abdominal Operations was the subject of a paper by Dr. Marie B. Werner, of Philadelphia. The doctor reported a case on which she had operated where the ligature escaped through the fistulous opening, and cited a number of cases from the literature or from the personal reports of physicians to her. She related two cases where she removed one ovary and tube and had to reopen the abdomen later and remove the other.

Dr. W. H. Wathen, of Louisville, thought one of the most important subjects connected with abdominal section was that of sutures. The points of importance are good quality, aseptic, and not too large. They should be as absolutely aseptic as possible. He thinks very little of chemical antiseptics in ligatures. He never uses sutures which do not come to him in sealed boxes. He will not allow them to be handled by the instrument-maker and his many customers. He does not believe that in abdominal surgery we need use anything except silk sutures. He never leaves an ovary and tube unless there is a very great desire on the part of the patient to bear a child and the ovary and tube is apparently healthy. Otherwise he would always, when there is one ovary and one tube diseased, take out the other also.

Dr. A. F. Currier, of New York, thought that if we could not appreciate disease in the other ovary and tube we should not remove them. Whether the woman could have children or not was not germane to the question of operation. We should operate if it is demanded by disease. If not demanded, we should not operate.

Dr. T. A. Reamy, of Cincinnati, thought it none of the operator's affair whether a married woman wishes to have children or not. He should leave the healthy ovary, and he commits sacrilege who touches it.

Dr. H. A. Kelley, of Philadelphia, said he had operated on about forty cases of pus tubes. In every case but one he removed both ovaries because he found both tubes diseased. In this one case he had to reopen the abdomen in a short time and remove the other tube. Most operators think it the best plan to remove both tubes, but he should not do it did he think one was healthy. He has had several cases where sutures came out through fistulæ. When he sees a fistulous tract in the abdominal wall he tells the patient that it will keep up till one or two little knots of ligature come out, and he is generally justified in his conclusion. The ideal ligature is a well-prepared catgut. He is now about to enter on some experiments with catgut prepared after the method of Doederlein, of Leipsic, that is, by dry heat.

Dr. F. C. Meyers, of Fort Wayne, preferred the silkworm suture. He removed one ovary from a lady in 1874, and left one. The lady immediately became very prolific, showing that there was a healthy ovary somewhere.

Adulterated Silk.—Dr. A. W. Johnstone, of Danville, Ky., said that when he bought his silk sutures in America he often had his ligatures come through the drainage-tube. Since buying them in England he has had whole handfuls of ligatures left in the abdomen to disappear entirely. Our silk is adulterated. It is one-tenth flax, hemp, or some vegetable matter, which will not absorb. Pure silk, if placed in caustic potash, will disappear as a thread, and can be spread about like collodion.

Imperfect Operation.—Dr. Joseph Price, of Philadelphia, thinks that when sutures appear in the fistulæ it is due to an imperfect operation. Too many tie the tubes too far from the cornu—one to one and a half inch. This left unhealthy broken-down matter, which can be scraped away with a curette, and which is not unlike a broken-down gland. When he had sinuses he would in the vast majority of cases do the operation over again and go to the bottom of the trouble. We will find a cheesy, diseased condition of affairs at the bottom of the sinus, with probably some attachments We have no right to endanger a woman's life for a possible conception. A hydro salpynx is often as virulent as a pus tube, and hence if found on one side remove the other also, unless we are anxious to do a second operation.

Dr. T. A. Reamy, of Cincinnati, had probably done this operation as often as any one in the house. He did not speak of conception in a sentimental but in a scientific manner. The conception was the test of the cure.

A Plea for the General Adoption of the Traction Forceps was the subject of a paper by Dr. Joseph Hoffmann, of Philadelphia. He favored the forceps very much, and did not believe in the short forceps as the traction forceps did the work. In using the traction forceps the force applied is in the centre of the fenestration, and hence injury is less frequent. The doctor discussed the merits of these forceps at length, and demonstrated the use of the forceps.

Dr. Joseph Price, of Philadelphia, was satisfied that the traction forceps have saved many children, and there is no harm in using them with the head on the perineum; in fact, they are in many cases the means of saving the perineum. He had used this traction for over an hour on his own child, with the occiput in the sacrum, and had had no bad results.

A Retrospect of Pelvic Surgery was the subject of a paper by Dr. Joseph Price, of Philadelphia. He attacked the conservative surgeons, who, he said, were riding on a popular wave because conservatism meant safety. They were men of inexperience, their cases operated on had died, or if young men they had been carried off by electricity. Electropathy, hydropathy, and homœopathy are the three great frauds. Results of all these operations depend very much on the experience and training of the men who operate.

Drainage in Abdominal Surgery was the subject discussed by Dr. George E. Shoemaker, of Philadelphia. No tube is better than a badly managed one. If a tube remains in for forty-eight hours it will tide over the dangerous period and not interfere with the cicatrix. Pressure of the ends of the tube may cause sloughing of the intestine. To prevent this, lift the tube one-half inch each day, and permit it to return to its place. If a tube needs emptying only once in twelve or twenty-four hours its presence is unnecessary.

Dr. H. C. Meyers, of Fort Wayne, Ind., resorted to drainage in a great many cases. If etherization was prolonged, or patient prostrated so as not to be able to reabsorb serum, introduce a tube to carry it off.

Papers were read by Drs. Ree, of Cincinnati, and Greenby, of Kentucky, and several read by title, after which the Section adjourned.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH.

Sixth Annual Meeting, held in Brooklyn, May 27, 1890.

William McCollem, M.D., President, in the Chair.

After some opening remarks by the President, and the transaction of the business of the Branch, Dr. John Shrady read a "Memoir of the late Isaac E. Taylor, M.D."

Dr. Charles A. Leale, read a "Memoir of the late Charles S. Wood, M.D."

Biographical sketches of Dr. Lewis Hall Sayre, and other deceased Fellows, were read by title.

Observations on Rheumatism, Especially as Involving the Tonsils.—Dr. William Henry Thayer, of Brooklyn, read a paper on this subject.

Within a few years, he said, different observers had noted the occurrence of rheumatic inflammation in tissues and organs not previously recognized as liable to its

invasion. Having referred to a number of these affections, such as rheumatic pneumonia, bronchitis, pleurisy, and pharyngitis, he said that the relation of tonsillitis to rheumatism in any case had never been noticed until a very recent period. The only experience that had, as yet, been published, was that of Dr. C. W. Haig-Brown. In a paper entitled "Follicular Tonsillitis and its Relation to Rheumatism," which appeared in the *British Medical Journal* in September, 1889, he related the frequency of tonsillitis and of rheumatism in a public institution, due, as he thought, to fever exhalations. As the result of his observations, he wrote: "Having so far established a causation and clinical relationship between rheumatism and tonsillitis, we are led to one of certain conclusions: That rheumatism is a general disease which as frequently finds expression in the throat as in the fibrous and serous membranes; or, that the inflamed tonsil is the receptacle for the rheumatic poison and the medium for its conduction to the general circulation; or, finally, that specific germs find their way into the body under circumstances favorable to their entry, and then evidence their presence in inflammation of the tonsils and the fibrous and fibro-serous membranes."

In the winter of 1888–89 Dr. Thayer said he saw six cases of rheumatic tonsillitis, and he proceeded to give a detailed account of these. The first was that of a boy, twelve years of age, who, in five consecutive months had five attacks, and, after nine months' freedom from illness, three more attacks, in the course of two months, of tonsillitis or rheumatism, or both combined. The second case was that of a commercial traveller, aged forty, the subject of alcoholism, who suffered from acute rheumatism of the arms and neck, tonsillitis, and gonorrhœa. The third patient was a girl, seventeen years of age, who had an attack of tonsillitis in connection with rheumatism, the latter first affecting the shoulders and insteps and afterward going from joint to joint, though with little swelling. The fourth was a lady, aged thirty, who had moderate follicular tonsillitis in connection with rheumatic pains in the neck, chest, abdomen, and leg. The fifth was a young girl, aged sixteen, who had a severe attack of acute articular rheumatism following quinsy with purulent discharge. He reported that she had quinsy in 1886 and 1888, the last attack being followed by articular rheumatism, continuing nine weeks. The sixth case, was in a married woman, thirty years of age, who had follicular tonsillitis with subacute rheumatism.

He then related a seventh case, in a boy aged twelve, which he said was of especial interest as an instance of rheumatism involving a derangement of lymphatics. Enlargement of the submaxillary, sublingual, and other glands, together with the rheumatic trouble, seemed to terminate in an explosion of cellulitis of the whole side of the face.

Some of these cases, he thought, might constitute a desirable contribution to the study of the physiology of the tonsils, which had enlisted the attention of various physicians within the last few years. Having referred to the theoretical views of Drs. R. Hingston Fox, S. Spicer, and others, he stated that Dr. Eugene Hodenpyl, of Brooklyn, had been devoting much time and care to experiments upon living animals, and to microscopic examination of the faucial tonsils, with results which had not yet been published but which he was permitted to present. Some of the conclusions arrived at were as follows: None of the theories thus far advanced to explain the functions of the tonsil are conclusive. The tonsils are not absorbing organs. They neither absorb fluids nor solid particles from the mouth, under ordinary conditions, nor do they take up foreign materials from the tissues in their immediate neighborhood.

Some Personal Observations upon the History and Claims of Hypnotism, and its Employment in Certain Diseased Conditions.—Dr. H. Ernest Schmid, of White Plains, read a paper on this subject. From his own individual experience he said that he felt able to prove beyond doubt the value of this new but now scientifically accepted therapeutic means, especially in these days of neuroses of all kinds. Not very long since he had, like a large number of other physicians of the present day, treated the claims of hypnotism with derision, but he did not hesitate to admit that this opinion was one based simply upon ignorance. Unmistakable results had so greatly changed his views that he had come to speak a word in defence of what he had formerly been inclined to ridicule.

Having remarked that when we reflected on the latest achievements of science in other directions it became an easy matter to broaden the foundations upon which we stand by admitting that what has been accomplished seemed at one time far more impossible than the claims of hypnotism; he said it was an acknowledged fact that intellectual and moral phenomena can be communicated to others, not by a microbe, but through that imitative faculty which all men possess to a greater or less degree. In this connection he alluded to the epidemics of suicide which have been noted from time to time in various parts of the world, in which this crime seemed to be propagated by a sort of moral contagium. He held that every act of imitation was a transfer of a brain movement communicated to another in such a manner that the brain which repeats this movement of the first brain adopts it as one of its own originating. On this, to his mind, rested the great problem of hypnotism; and even among animals, such as dogs, this imitative power had been observed.

But even diseased brain manifestations could produce similar phenomena in other beings; though, of course, the soil must be suitable for receiving impressions. All were familiar with the fact that gaping is contagious, and also that St. Vitus's dance and epileptic seizures are sometimes communicable. Not a few alienists had expressed the belief that mental aberration may be communicated to a sound mind by example and daily intercourse with the insane. It was astonishing to find, on examination, to what extent our intelligence was impressed by favorable as well as unfavorable surrounding influences. There existed within us a secret force which constantly conformed our thoughts to our actions, and our entire inner being to our external habits. Therefore, if we were induced to commit wrong actions by contagion, as it were, our inward being would mould itself in conformity with them; and hence it did not take a great deal to plant in a person (especially in youth) false ideas, and thereby to cloud the sound mind and cause him to lose his clear reasoning.

Hypnotism was the imparting of a brain movement to others, or the creating of a new one in another, which became as the other's self-originated thought. The only peculiar feature about it was the condition that could be produced in the majority of persons, in which they were most ready to receive and adopt these foreign thoughts as their own. He had nothing to say on the point which had been raised by some, that hypnotism is detrimental to the spiritual or mental health of the persons experimented upon. If dangers should come from it (though he did not see how) had we not many therapeutic means that *might* prove dangerous?

Having referred to the conflict among the followers of hypnotism, headed on the one side by Charcot and on the other by Professor Bernheim, of Nancy, he said that "suggestion" to him meant simply a species of psychic influencing, differing, however, from all others, such as the command, the communication, or the teaching. In being commanded in the waking state there always existed in the obeying subject's brain a degree of questioning or criticising, whereas during hypnotic sleep this was, not the case, and the suggestion was carried out without any examination as to its intrinsic value at all. As had been stated, the thought, the idea, the impulse to act was in the hypnotized person, received, adopted, absorbed we might say, and regarded as originated within his own brain; and the hypnotic state produced a capacity for concentrated brain power unknown during the waking state.

If diseased conditions or emanations of the brain could

be produced by securing them in others (as there was abundant evidence to show), why, he asked, is it not possible, reversely, to make the brain conquer diseased conditions? To put it more logically: If the brain can be so influenced as to produce in the body a diseased condition, why is it impossible to expect the reverse, *i.e.*, to impress the brain with the strong desire to remedy a diseased condition of any part of the body, as long, especially, as it is of a functional nature?

Having stated that hypnotism was simply a development out of the so-called animal magnetism, he gave a sketch of its history, tracing it back to the occult science of astrology, which had naturally died, but had left certain results behind it. After following it down to the present time, he said that, in 1878, Charcot made demonstrations with it, and exhibited the physical condition of hystero-epileptics during the hypnotic state, and, in 1881, Paul Richet published in his book on the "Grand Hystérie," many hypnotic experiments in the same spirit as Charcot; but no public scientific acknowledgment of the claims of hypnotism upon scientific considerations was made till the medical faculty of Nancy became interested in the subject. Then, in 1886, was given to the world Professor Bernheim's interesting work, containing a full account of his individual experience with hypnotism. The Society for Psychical Research, in England, had been devoting much time to the subject, and Hack Tuke had for years past pointed out its therapeutic importance. In Switzerland great work had been done for it by the distinguished alienist Forel, and from his influence had emanated the great interest awakened for the study of hypnotism in Germany.

Dr. Schmid stated that he had carefully studied whatever he could find in print bearing upon the subject, and for some time past he had employed this important therapeutic means with excellent results in appropriate cases. He then proceeded to give in detail four sample cases in which he had used hypnotism with success. The first was a case of hysterical insanity; the second, one of violent ovarian neuralgia in a young lady of highly nervous organization; the third, one of subacute rheumatism of the wrist; and the fourth, like the first, one of hysterical insanity. In all complete cures were effected. In conclusion he quoted a passage from Maudsley, illustrating some of the points that he had been endeavoring to bring out, which was in part as follows: "Perhaps we do not as physicians consider sufficiently the influence of the mental states in the production of disease, and their importance as symptoms, or take all the advantage which we might take of them in our efforts to cure it. Quackery seems to have got hold of a truth which legitimate medicine fails to appreciate and use adequately. Assuredly the most successful physician is he who, inspiring the greatest confidence in his remedies, strengthens and exalts the imagination of his patient. If he orders a few drops of peppermint-water with the confident air of curing the disease, will he really not do more sometimes for the patient than one who treats him in the most approved scientific way, but without inspiring a conviction of recovery? . . . Entirely ignorant as we are, and probably ever shall be, of the nature of mind, groping feebly for the laws of its operations, we certainly cannot venture to set bounds to its power over those intimate and insensible molecular movements which are the basis of all our visible bodily functions, any more than we can justly venture to set bounds to its action in the vast and ever-progressing evolutions of nature, of which all our thoughts and works are but a part. This much we do know, that . . . in the microcosm of the body, which some ignorantly despise, there are many more things in the reciprocal action of the mind and organic elements than are yet dreamt of in our philosophy."

Dr. C. A. Leale said that while in certain cases the use of hypnotism might be attended with benefit, he should like to utter a word of warning. He accordingly related the case of a young girl who, while in the hypnotized state, suddenly developed the most violent mania, which lasted for several months and required her confinement in an insane asylum.

Dr. Schmid said that he did not think such a case should deter us from the use of hypnotism in suitable cases, as it seemed to him that the acute mania was merely a coincidence. It was a matter of not uncommon experience with those accustomed to treat the insane that mania should develop in this very sudden manner.

Ectopic Gestation, especially with Reference to Diagnosis and Therapeutics—Dr. George T. Harrison, of New York, read a paper on the above subject.

In some preliminary remarks on the pathology of this anomaly, he said the doctrines recently taught by Lawson Tait and John Strahan were diametrically opposed to the truth. In regard to etiology, partial peritonitis, producing flexion and constriction of the tube, was, as stated by Virchow, a potent factor in the production of tubal pregnancy. The changes produced in the tube by catarrh and blennorrhœa were also a frequent cause of this variety. Myomata of the uterus and polypi of the tube in some cases played a conspicuous rôle. As a matter of positive knowledge it might be stated that in all cases of ectopic gestation the uterus during their development underwent the same changes as in the beginning of normal pregnancy.

As to the possibility of ovarian pregnancy, Virchow had recently declared that in his opinion no doubt could exist in regard to its occurrence, and in Winckel's text-book on obstetrics there was an illustrative drawing of a beautiful example of this form of extra-uterine pregnancy. Whether primarily the fertilized ovum could become attached to the peritoneum and undergo development (abdominal pregnancy) was a matter of doubt, because it had not been certainly demonstrated that tubal and ovarian pregnancy could be excluded in the cases heretofore investigated.

In tubal pregnancy, which was the form most frequently met with in practice, the rupture, which ordinarily took place early in pregnancy, might occur either into the broad ligament or at the upper periphery of the tube into the abdominal cavity. The doctrines taught by Tait and adopted by Strahan, upon the relations of tubal pregnancy to retro uterine hæmatocele were radically wrong. What he called extra-peritoneal hæmatocele ought to be called peri-uterine hæmatoma, or simply hæmatoma; while the term retro-uterine hæmatocele should be limited to those blood tumors occasioned by effusion of blood into a part of the peritoneal cavity segregated from the rest of the cavity by pseudo-membranes, Douglas's pouch usually being the seat of this effusion. What Tait called an intra-peritoneal hæmatocele was not a hæmatocele at all, but a free effusion of blood into the abdominal cavity, there being no tumor displacing the uterus forward. If, however, after rupture of a tubal pregnancy, the extravasation of blood took place at a part of the abdominal cavity by pseudo-membranes (which would naturally be Douglas's pouch, between rectum and uterus), the blood would separate the walls of this space, displacing the uterus forward, encroaching on the space of the rectum, and forming, as a rule, a globular, well-defined tumor.

Such blood tumors could also be formed by a somewhat different mechanism, that is if the hemorrhage persisted for some time and was moderate in degree, and the pelvic cavity was closed above by blood coagula or by inflammatory adhesions. Effusion of blood into the broad ligament gave rise to a blood tumor beside the uterus, a true hæmatoma. The correctness of these views was attested both by clinical data and post-mortem observations; and in at least three instances Dr. Harrison was enabled to diagnosticate positively the existence of adhesions between the uterus and rectum, the remains of previous partial peritonitis, in the subjects of which hæmatocele was subsequently developed. The two conditions, retro-uterine hæmatocele and hæmatoma, could, as a rule, be readily distinguished. Tait simply ignored the exist-

ence of hæmatoma in its true significance; there being for him only extra peritoneal hæmatocele, properly called hæmatoma, and free extravasation of blood into the abdominal cavity. To refute this error it was only necessary to quote the high authority of Virchow and of such competent observers as Ziegler, Klebs, and Coates.

As demonstrated by Karl Schroeder, rupture of a tubal pregnancy was one of the most frequent causes of retro-uterine hæmatocele. The cases of Hart, Coates, Maury, and others proved that the rupture might take place into the broad ligament and result in the formation of a hæmatoma; but the facts of pathological anatomy and clinical observation in other cases could only be explained on the hypothesis that the above explanation of the origin of retro-uterine hæmatocele was correct.

In regard to the possibility of diagnosticating ectopic gestation in the early months of pregnancy he quoted Tait's opinion in the negative, and remarked that such scepticism was unjustifiable in the light of recent experience. He had himself seen four cases of tubal pregnancy prior to rupture, and in one of them the diagnosis was confirmed by the extrusion of the decidual membrane from the uterine cavity. It was true, however, that these cases were not generally seen until rupture had taken place. Dr. Harrison said he concurred fully with Veit in regard to a diagnostic sign to which he had called attention. This was the peculiar softness of the pregnant tubal sac, and it was not found in any other variety of tubal tumor. In addition, the pregnant tube showed a degree of elasticity peculiar to itself. After blood had been effused into the tube the differential diagnosis became much more difficult, since under these circumstances the tube was much more tense and harder to the touch.

As a rule, women who were the subjects of ectopic gestation did not invoke the aid of the physician until symptoms of rupture had appeared. The clinical phenomena then presented were those of a free hemorrhage into the abdominal cavity, or those pertaining to hæmatocle or hæmatoma. The diagnosis was made absolutely certain if decidual membrane was extruded from the uterine cavity accompanied by moderate hemorrhage. In the later months of ectopic gestation the diagnosis of pregnancy was generally easy; but the demonstration of the fact that the fœtus was outside of the uterus might offer difficulties. Accurate bimanual palpation, however, would ordinarily lead to the recognition of the true condition.

In the matter of treatment, Dr. Harrison said he was in entire agreement with the views of Olshausen. In the first months, before rupture, if the diagnosis seemed certain, laparotomy was indicated. After rupture had occurred, during this period, operative interference was indicated only when the symptoms assumed a threatening character. When the first months had passed, if the ovum continued to grow, operation was called for, and the sooner the better. If possible, the entire fœtal sac should be extirpated. If not, it should be sutured to the abdominal coverings and drained above. In individual appropriate cases the future would have to decide whether it is not best to leave the placenta and immediately close the abdomen. Electricity, while it would destroy the fœtus, would not cure the patient.

The President said that there were but few skilled operators, even in the large cities, and it seemed to him that for the mass of practitioners, and especially in the country, electricity must still be regarded as the treatment *par excellence* for ectopic gestation.

Dr. McGillicuddy spoke of the many mistakes that were made in diagnosis, and said that he had once been present when a well-known gynecologist performed laparotomy for salpingitis, but found to his surprise on opening the abdomen that extra-uterine pregnancy was present.

Dr. Harrison said, in reply to the President, that in almost every district in the country there was some surgeon competent to operate. In the early part of gestation the operation was in fact an extremely easy one; and the case of Dr. Janvrin, in which the patient died after the fœtus had been destroyed by electricity, showed the danger of depending on that mode of treatment.

Surgical Treatment of Cough in Diseases of the Upper Air-Passages, with Demonstration of Instruments and Specimens.—Dr. J. W. Gleitsmann, of New York, read a paper on this subject. Among the affections treated of were adenoid vegetations of the vault of the pharynx, hypertrophic rhinitis, deviations and exostoses of the nasal septum, and hypertrophy and other abnormal conditions of the faucial, pharyngeal, and lingual tonsils.

The Radical Cure of Hernia.—Dr. Thomas H. Manley, of New York, then presented five or six patients, ranging from infancy to old age, on whom he had operated for "the radical cure of hernia" by the McBurney method.

AMERICAN PEDIATRIC SOCIETY.

Second Annual Meeting, held at Mott Memorial Hall, New York, June 3 and 4, 1890.

J. Lewis Smith, M.D., President.

Address of the President. — After some words of welcome by the President he referred to the important position which pediatrics had of recent years come to take among the special branches in medicine, and then mentioned some of the work done by Americans and members of this Society the past few years, which was likely to prove enduring—for instance, the operation of intubation, and the publication of the "Cyclopædia of Diseases of Children," an ably conducted journal of pediatrics. He thought it best for this Society to remain entirely distinct from any other; that the meetings should be held in the fall, perhaps the third week in September; that its membership should be drawn from the whole of America, and made special reference to South America and Mexico; suggested that the two special subjects for discussion called for by the constitution be announced each year six months before the meeting; that the general programme be issued a month before the meeting; that, following the precedent furnished by the Pediatric Section of the Ninth International Medical Congress, members who have opinions which which seem important, or facts which throw light on the subject, and do not have time to present them during the discussion, may present them in writing as briefly as possible to the Secretary.

Management of Human Breast-milk in Cases of Difficult Infantile Digestion.—Dr. T. M. Rotch, of Boston, in this paper gave an analysis of the human milk in a series of cases—during the time of healthy digestion, and also during indigestion in the infant, showing, at the same time, the bearing of the mother's health and habits, and the amount and quality of food taken, upon the character of the milk.

Physicians acknowledged that the maternal breast-milk (meaning thereby the average) was the best diet for the infant, but did not seem generally to fully realize the importance of their admission, for not infrequently they forbade the use of this food, and ordered a wet-nurse, or hand-feeding, when the infant showed indisposition more or less marked, without taking the trouble to analyze the milk, or inquire into the reasons for its possible unwholesome qualities. Brief reference was made to the various conditions affecting the quantity and quality of the milk, such as the state of the mother's health, exercise, food, mental emotions, length of the intervals between the nursings, etc. The longer the intervals the greater the proportion of the watery elements. In a general way the milk could be looked upon in its normal condition as a secretion, yet as colostrum and under certain unfavorable conditions it took on to a considerable degree the characters of an excretion. Marked variations in the milk were almost always shown in the amount of fats and albuminoids which it contained; and, consequently, we treated almost universally these elements. Meat, and a nitroge-

nous diet increased the fats in milk, while a diet of fat had not this effect. The albuminoids were more difficult to deal with. To lessen them, he had found in practice the best means was, if the woman were in health, to increase the amount of exercise—preferably walking in the open air. One to two miles a day was the walk required by the average woman. In the diagrams presented, containing an analysis of the milk in several cases of difficult digestion, there was usually an increase in the amount of albuminoids, sometimes up to or beyond four per cent., with or without a change in the fats, and treatment which resulted beneficially to the patient had the effect of reducing the albuminoids. He had not known an abscess to follow the use of the pump on the human breast, and exhibited a simple and efficient instrument of this kind. If one had to deal with a case in which there was very poor milk, this should first be made rich, and afterward the constituents be altered as required. But there were cases in which, in spite of following out the rules contained in the paper, we were unable to manage the milk, and make it suitable food for the infant. Nor were there fixed limits as to the proportion of albuminoids and other ingredients that should be present. Each case must be studied by itself.

In the discussion appreciation was expressed of the value of work in this special direction.

Spurious Meningocele ; Presentation of Patient.—Dr. F. Huber, of New York, read the paper and presented the patient, a girl, nine years of age, in whom the spurious meningocele followed the use of the forceps during labor. There was a fluctuating tumor over the right parietal bone, covered by the scalp, a fracture of the bone, and probable communication with the lateral ventricle, for tapping had shown the fluid to be cerebro-spinal. It recurred after each tapping, and had existed until to-day. The child had epileptic attacks, due probably to cortical changes. The literature of the subject was not extensive. In conclusion, he stated the following propositions : Simple fractures of the vault in children, involving the membranes and brain, may be attended by one of two possible complications. In the one variety we notice a cranial gap and the brain in direct apposition, with bone pulsating at the bottom of the opening ; in the second we have a false meningocele ; the watery tumor may communicate with the interior of the skull, or the opening close subsequently to the injury by bony or fibrinous union. False meningocele may be primary or secondary. It is primary when it complicates a simple injury fracture ; secondary when it occurs after compound fracture, trephine, or other operation on the brain. As a primary condition it is peculiar to children. If pulsation be present or pressure on the tumor give rise to intracranial symptoms, the communication with the interior is patent. It must not be forgotten, however, that the opening may be small, or several, or in a tortuous direction, and pressure not give rise to intracranial symptoms. The presence of the meningocele is proof positive that the lateral ventricle has been involved. It may develop at once, or after days, weeks, or even months. The operative measures may be curative or palliative.

On what Early Symptoms may We Rest a Diagnosis of Tubercular Meningitis?—Dr. W. P. Northrup read the paper, in which he gave a graphic picture of the symptoms in a case of tubercular meningitis, also related some cases of gastro-entero-colitis, and one of pneumonia with cerebral symptoms, all of which illustrated the difficulties in differentiating tubercular meningitis. He asked the members what they regarded as the four most reliable signs of tubercular meningitis in early life, meaning prior to the second year. His own answer would be, first, persistent vomiting ; second, irregularity of pulse ; third, irregularity of respiration ; fourth, apathy (dulness with a mark on the countenance, or dead look).

Dr. C. W. Earle, of Chicago, thought that, with the exception of vomiting, the symptoms mentioned by Dr. Northrup were not early ones, and they were more characteristic in children over, than in those under, two years. And the vomiting should have been described as cerebral—projectile. As a matter of fact the diagnosis was very difficult and uncertain, but if he were to undertake to mention three most important early symptoms in early life they would be—a long prodromal period which indicated that something was coming on, the cerebral vomiting, and a history of hereditary taint or trauma. Later there was local spasm, etc.

All Signs may Fail.—Dr. Rotch said all these signs might fail, the case come to the post-mortem table with diagnosis of tubercular meningitis, and some other condition be found the cause of the symptoms and death ; or no lesion at all be found, for there were affections of the vaso-motor and pneumogastric systems which might produce the symptoms mentioned, and even prove fatal, yet our present methods fail to reveal any changes at the autopsy. Projectile vomiting was not always an indication of cerebral or meningeal lesions ; he had seen it in otalgia starting from the teeth, and ptosis and inequality of the pupils might be produced by simple irritation of the tympanum in the young. Thus we should be careful in laying down diagnostic rules in diseases of early life where almost all symptoms might be initiated by reflex nervous troubles. He protested especially against apathy being regarded as an early sign of tubercular meningitis.

Dr. A. Jacobi thought that, in the majority of cases, finding the symptoms named by Dr. Northrup, and connecting them with the other points in the history, one would be right in making the diagnosis of meningitis, but he should not be too certain of it. For he had seen, for instance, irregular pulse, long continued, in anæmia ; projectile vomiting did not occur unless the tubercles involved the meninges at the base, and the meningitis need not be tubercular in order to have these symptoms. The temperature had not been included among the four symptoms, but he could say it was more generally at this period not elevated. In the beginning stage, that of irritation, the child was seldom seen by a medical man ; it was not until vomiting occurred, or other special symptoms developed, that he was called. He would then find there had been a period of peevishness and sleeplessness. Unilateral symptoms pointed rather to this affection, bilateral to nephritis ; then we had also to consider the differential diagnosis between tubercular meningitis and the rheumatic, the syphilitic, and other forms.

Dr. Joseph E. Winters thought the four symptoms mentioned by Dr. Northrup, when properly or intelligently applied, could be relied upon with a great deal of confidence in diagnosis of this disease. The physician, should, however, exclude reflex causes, and then look carefully into the history, and observe the patient by the hour, especially while asleep.

A Subacute Affection.—Dr. A. Caillé called attention to the fact that tubercular meningitis was not an acute, but usually a subacute affection—a point to bear in mind in speaking of an early diagnosis. He could in many cases distinguish reflex cerebral symptoms from encephalo meningitis, but he would not undertake there to say positively the case was one of tubercular meningitis.

The Diagnosis not Early.—Dr. J. H. Fruitnight related two cases, in one of which the diagnosis seemed clearly that of tubercular meuingitis, the symptoms among others being those mentioned by Dr. Northrup ; but he said he saw the patient only after ten days or two weeks, as was the rule, and at this period it was too late to call our diagnosis early.

Three of the Four Signs Absent.—Dr. W. P. Watson referred to two cases, in one of which the diagnosis of tubercular meningitis was confirmed by Dr. Jacobi. The patient died. Yet the symptoms relating to vomiting, the pulse, and respiration, mentioned by Dr. Northrup, were absent.

Dr. Earle thought tubercular meningitis not as common as formerly, and in reply to his question whether such was the observation of others, Dr. Rotch replied in

the affirmative, and the President said that in New York City we more commonly make the diagnosis of cerebro-spinal fever or meningitis, while formerly more cases were reported as tubercular meningitis.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 27, 1890.

A. S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

Remarks on the Sterilization of Milk Food, with a Demonstration of the Different Forms of Milk-Sterilizing Apparatus now in Use.—DR. AUGUST CAILLÉ presented this subject. Methods of preserving food consisted in boiling and keeping them from exposure to germs, or in freezing. One of the most important articles, and at the same time one of the most unstable, was milk. Diarrhœal diseases were now regarded as belonging among those caused by germs, and a frequent source of them was impure or spoiled milk. Credit was due to Soxhlet for first devising a method of sterilizing milk for use in the household (1886). Since then various methods had been brought forward, all of which were modifications of Soxhlet's, among them being Escheric's, Wilson's, Arnold's cooker, Seibert's, Koplik's, etc. Then there were two reliable firms which sterilized milk at the dairy in the country and shipped it to the city. In all the methods the milk was placed in bottles, a stopper inserted, admitting of the escape of air and gases at the beginning of the heating process, set on a tray in a vessel which stood above water at the bottom, the cover then applied and the water made to boil about forty minutes. The stopper might consist of cork with a glass tube in the centre, of cotton, or of rubber with a channel a part of the distance on one side. If necessary the family could make their own tray, and use an ordinary tin vessel with a cover, and nursing-bottles.

Uses a Wash-Boiler.—DR. HENRY KOPLIK had found that some mothers would not sterilize milk for their children, and preferred to buy it if sold at a very reasonable figure. He therefore had improvised an apparatus for sterilizing milk in a number of bottles at one time. It was the ordinary method, except that a wash-boiler was employed, surrounded by some non-conducting material. Before putting the milk into the bottles they were exposed to heat in an oven at 150° to 180° F., for an hour. The ideal cork, he said, was cotton. While milk might remain sterilized and pure for weeks or months, he did not believe in giving it to children when more than three days old.

The Weight of the Baby should Determine the Quantity of Food.—DR. SEIBERT stated some objections to Soxhlet's apparatus, and described his own, in which rubber corks were used, cut out part the way up one side to allow escape of gases until pushed entirely in. An essential point in his method consisted in bottles of graduated sizes in accordance with the weight, not the age, of the baby.

Double Hydrosalpinx; Pedunculated Fibroid of the Uterus.—DR. H. T. HANKS presented the specimens. The case was of interest as showing clearly that in some instances hydrosalpinx could be cured only by an operation. This patient's symptoms began six years ago, following exposure, consisting in part of attacks resembling pelvic peritonitis. She was at different times in hospitals in London, under Duncan and Barnes, who felt fluctuating pelvic tumors and recommended an operation, but it was refused. Dr. Hanks operated May 7th, removing tubes, one of which contained half a pint, the other seven ounces of fluid, and also a pedunculated fibroid from the fundus of the uterus. Recovery was uninterrupted.

The Immediate Operation for Lacerated Cervix.—DR. ROBERT A. MURRAY thought a sufficient reason for presenting a paper on this subject was the fact that operations for the repair of the lacerated cervix were the most frequent of those performed by gynecologists. The arguments in favor of immediate repair of the perineum, an operation which was generally accepted by obstetricians, were repeated in favor of immediate repair of the cervix. Yet in the latter injury immediate operation was very seldom resorted to, although it had been advocated, together with the immediate operation for all other lacerations occurring during labor, as long ago as seven years by Dr. Pallen. While in the cases in which the author had employed it the laceration had been considerable in degree, and attended by no slight amount of hemorrhage, yet he thought it should be resorted to in all cases except those in which the tear was slight. It was especially indicated where this injury was attended by marked hemorrhage; where the circular artery was involved there was only one proper procedure, namely, to suture.

The only difficulty experienced during the operation was in passing the first suture at the angle of the wound. The parts were soft and relaxed, the cervix could easily be drawn down by the vulsellum forceps, pressure was made over the uterus by an assistant; the sutures should not be twisted or tied too tightly, lest they cut through the softened tissue. The object was merely to keep the surfaces coaptated. The parts were so benumbed during labor that an anæsthetic was not called for. If the patient were on the back, two assistants would be necessary to hold the legs in the lithotomy position. There should always be an examination for laceration of the cervix when more hemorrhage than usual took place, and especially if the pulse were at all affected. Two fingers being introduced, if there were a tear the rim of the cervix would give more at that point. A notch would be felt approaching nearer the vaginal junction than at the rest of the circumference, and warm blood would course over the finger. He had operated three times, without a speculum or other instrument except those usually carried in the pocket-case. In two he used silver wire, in one catgut. He had been led to do the operation to prevent puerperal inflammation, either local or general, and to avoid a slow convalescence seen in some cases after labor, even when unattended by elevation of the temperature.

Some Objections to the Operation.—DR. H. C. COE had performed the immediate operation in but one case, and then because the tear involved the circular artery. A laceration of the cervix after labor was a contused wound, and if it were sutured we might or might not get union, might or might not prevent sepsis. If suppuration occurred there would be greater danger of sepsis than if the wound had not been sutured. In the case on which he operated, the technique was extremely difficult. Then as to hemorrhage from the circular artery, it was extremely rare, and we were likely to suppose hemorrhage came from the lacerated cervix when in reality it came from a tear from the vagina. He referred to a case in which he felt sure before the patient left the hospital there was a bad tear of the cervix, but subsequent examination revealed none demanding an operation. Ordinary antiseptic precautions would guard against sepsis and render the immediate operation unnecessary.

DR. H. J. BOLDT was satisfied there were few cases in which the tear was so extensive as to demand the immediate operation; besides, it was difficult to detect minor injuries to the cervix, and under cleanliness they would heal. He thought the immediate operation more difficult than the secondary.

DR. A. P. DUDLEY thought the chief objection to the immediate operation would be that it might prevent free drainage from the uterus. He would use catgut, and operate only where the tear was considerable and attended by more than ordinary hemorrhage. He thought the hot-water douche would cause ordinary lacerations to heal.

DR. H. T. HANKS also thought the immediate operation would only be called for to arrest hemorrhage or in marked lacerations.

Dr. Murray said he would believe the hot douche would cause the lacerated cervix to heal after labor if it could be shown to do so in lacerations made by the scissors, as in the secondary operation if sutures were not inserted. The cervix, during labor, was much elongated, and could easily be reached for the operation. There was less danger of secretions becoming pent up than after the secondary operation; the ring was simply completed, the canal was large, the tissues patulous; the sutures simply approximated the tissues, and made no after-tension, but rather became loose during the process of involution. This process of involution also accounted for apparent healing of lacerations in many cases, while douches had nothing to do with it except to keep the parts clean. But, as in the case of the perineum, the tear only partially united, and when considerable at least should be sutured.

To Reduce the Initiation Fee.—Dr. Avery gave notice that at the next meeting a resolution would be offered, to reduce the initiation fee from five dollars to one dollar.

Correspondence.

A WORTHY OBJECT.

To the Editor of the Medical Record.

Sir: An effort is being made to raise a fund for the aid of Dr. J. Hancock Douglas, who is now a patient in the Presbyterian Hospital in this city.

Although this is not to be limited to the medical profession, it is hoped that the professional brethren of Dr. Douglas will do something for his relief.

Dr. Willard Parker, No. 50 West Ninth Street, has kindly consented to receive contributions for this purpose.

Very truly yours,

T. Gaillard Thomas, M.D.

600 Madison Avenue, June 9, 1890.

THE DEGREE OF HOSPITAL GRADUATE.

To the Editor of the Medical Record.

Sir: I am heartily in favor of the establishment of the degree of Hospital Graduate, as proposed by Dr. Abbott. A physician's clients often want to know what opportunities for study and what experience he has had without subjecting him to a cross-examination.

The additional letters necessary to give this information are easily added, will soon be understood, and are not as cumbersome or inelegant to most minds as we must infer they are to the mind of Dr. R. Ellis, to judge from his letter in the Medical Record of April 19th.

Before me lies a pamphlet by "Henry Drummond, F.R.S.E., F.G.S." At hand is a volume by "John Charles Bucknill, M.D. Lond., F.R.S., F.R.C.P." I am glad to learn so readily the facts stated in these abbreviated degrees, and no thought of cumbersomeness crosses my mind. Surely Dr. Ellis has met with many such instances in his reading; does he condemn the whole custom because possibly there are some men who have gained these degrees by other than "hard work?"

Dr. D. S. Maddox, in a letter published in the Medical Record for May 10th, says, "In almost every community may be found men who, although never internes in a hospital, are nevertheless thoroughly competent to treat any medical or surgical case they may be called on to attend." He instances Marion Sims and Ephraim McDowell. Let us apply this style of argument to a different department of professional activity. The Rev. Dr. Howard Crosby never studied in a theological seminary, and even received the degree of D.D. from Harvard College before he had been ordained. By a parity of reasoning with that of Dr. Maddox it is idle for a church, in the selection of its pastor, to ascertain or inquire whether or not a candidate be specially educated in theology, since such a brilliant orator as Dr. Crosby has for a quarter of a century filled with complete acceptability and success an important pulpit in New York City.

Then, too, there are "natural bonesetters," who—in rare instances—are eminently successful in reducing fractures. Hence, forsooth, we should not approve any scheme whereby an educated surgeon affixes M.D. to his name as an evidence of the study and experience which the "natural bonesetter" had no opportunity to acquire.

Dr. Maddox tells us "Vanity is an inherent quality, peculiar to man and the genus pavo." Perhaps it is unkind to inquire to what genus envy is peculiar.

A. W. Ferris, M.D.

Sanford Hall, Flushing, N. Y.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 1 to June 7, 1890.

Lauderdale, John D., Major and Surgeon, Fort Ontario, N. Y. Leave of absence granted for one month, to commence on or about June 1, 1890. Par. 4, S. O. 123, Headquarters Division of the Atlantic, New York City, May 27, 1890.

Dietz, William D., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 131, par. 4, A. G. O., June 5, 1890, Washington, D. C.

Dietz, William D., Captain and Assistant Surgeon. Having completed at New York City the duties assigned him in Special Orders No. 29, April 30, 1890, Division of the Pacific, by direction of the Secretary of War, will return to his station in that Division. S. O. 129, par. 5, A. G. O., June 3, 1890, Washington, D. C.

McElderry, Henry, Major and Surgeon. Granted leave of absence for seven days, by direction of the Acting Secretary of War, to take effect upon the final adjournment of the Army Medical Examining Board. S. O. 127, par. 7, A. G. O., May 31, 1890, Washington, D. C.

Cleary, Peter J. A., Major and Surgeon. Granted leave of absence for six months, on surgeon's certificate of disability, by direction of the Secretary of War. S. O. 127, par. 4, A. G. O., May 31, 1890, Washington, D. C.

Willcox, Charles, First Lieutenant and Assistant Surgeon. Granted leave of absence for ten days, with the approval of the Secretary of War. S. O. 126, par. 16, A. G. O., May 29, 1890, Washington, D. C.

Official List of Changes in the Medical Corps of the United States Navy for the week ending May 24, 1890.

Crandell, Rand P., Assistant Surgeon. Ordered to the Naval Hospital, New York.

Berryhill, Thomas A., Passed Assistant Surgeon. Detached from Hospital, New York, and ordered to Hospital, Mare Island, Cal.

Anderson, Frank, Passed Assistant Surgeon. Ordered to special duty in the Bureau of Medicine and Surgery.

Van Reyper, W. K., Medical Inspector. Ordered to New York on special temporary duty.

Kite, J. W., Passed Assistant Surgeon. Detached from Naval Hospital, Pensacola, and to Hospital, New York.

Craig, Thomas C., Passed Assistant Surgeon. Detached from Naval Hospital, New York, and to the Vesuvius.

Anderson, Frank, Passed Assistant Surgeon. Granted leave of absence for the month of June.

Ogden, F. N., Assistant Surgeon. Ordered for examination preliminary to promotion.

White, S. S., Assistant Surgeon. Ordered for examination preliminary to promotion.

TREATMENT OF DIARRHŒA IN EARLY LIFE.[1]

BY HENRY DWIGHT CHAPIN, M.D.,

PROFESSOR OF DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, AND AT THE WOMEN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; ATTENDING PHYSICIAN TO THE DEMILT DISPENSARY.

THE proper management of common diseases is the daily problem of the practitioner of medicine. No subject is so trite or old to him but that a free discussion by his colleagues may throw some light upon it. It is well occasionally to stop and take account of our therapeutic stock, particularly in reference to every-day diseases. Perhaps no affection is so frequently encountered as the diarrhœa of infancy and early childhood. It is the potent cause of the high mortality in our cities during the summer season, and, as such, is a subject of constant solicitude and careful study on our part. As this mortality is largely, if not almost entirely, among artificially fed infants, the dietetic treatment assumes the first importance. All the recent advances in infant feeding have come from a close study and imitation of nature. As soon as bacteriology shows that human milk, as it comes from the breast, is absolutely sterile, and that cow's milk kept from twelve to twenty-four hours is full of bacteria, we understand why the latter so often disagrees with the infant. The method of sterilizing, as between boiling and steaming, is a point of some interest. Prolonged boiling of milk, while destroying the germs, produces other changes, such as the formation of a scum on contact with the air, consisting of coagulated albumin with a small modicum of fat. According to Dr. Townsend boiling expels about three per cent. of CO_2, N. and O. which may explain the flat taste of milk so treated. Unless the boiled milk is hermetically sealed, fresh germs of course gain access, and the good effects of sterilization are lost. Soxhlet's well-known apparatus, by means of which bottles with perforated rubber stoppers are immersed in boiling water, and then sealed by glass plugs, was the first practical step toward obviating this difficulty. This apparatus, however, is cumbersome and somewhat expensive, and in my hands has failed to thoroughly sterilize the milk, at least when following the printed directions. Thus the milk would frequently become sour in two or three days, showing an imperfect degree of sterilization. Sterilization by steam appears to be more thorough and complete than that effected by boiling in water. For the past year I have used the Arnold steam cooker, both at the Babies' Wards and in private practice, for the purpose of sterilizing milk, with much satisfaction. By this apparatus milk is brought to the temperature of live steam, and maintained at this uniform temperature for a certain length of time. Dr. Cheesman, who first called attention to the cooker as an efficient sterilizer of milk, noted the fact that boiling for a certain length of time in a vessel, the sides of which are exposed to the air, is not efficient, as the temperature in different parts of the vessel is found to vary considerably. This constitutes the main objection to Soxhlet's apparatus, the principle being that of a water-bath, while in the cooker we have a steam bath, in which any variation of the temperature is prevented. The printed circulars advise that the milk be heated from thirty to forty-five minutes. This period of time, however, is not sufficent to sterilize the milk very effectually, as it is apt to become sour in a few days. In a series of trials I have found that fully an hour and a half is necessary to sterilize the milk with any thoroughness, as it will then keep sweet for several weeks. If it is desired to preserve the milk for a longer period, it can be resterilized after a certain interval of time. Thus a bottle of milk that I sterilized on September 10, 1889, and resterilized on September 21, 1889, was opened on April 15, 1890, and found not to have turned sour. The Arnold cooker has the advantages of being comparatively cheap and easily managed. No complicated cork is employed, but simply a plug of ordinary cotton. An ordinary double boiler makes an efficient sterilizer, as I have proven by trial. This is to be found in many kitchens and can be procured at a small cost. The bottles of milk, after being plugged with cotton, are simply placed in the upper receiver, and the boiler put upon the stove for a suitable time. I have kept milk sweet for several weeks in this way, and believe this will prove one of the simplest and cheapest methods of sterilization. Simplicity and economy are elements extremely important in reference to sterilization, as the necessity of this procedure is greatest among the poor and inefficient. Even if a complicated apparatus could be procured, they would be unable to use it. I have occasionally sterilized milk by placing the bottles, with cotton stoppers, in an ordinary oven. It is important to sterilize the milk as soon as possible, as there are so many sources of contamination—first in the milking, and then in the transportation and transfer—by which germs may gain access to it. We are told that germs increase with great rapidity, many of them doubling every half hour, so that the necessity of early sterilization can be appreciated. If fermentation has well begun in milk, sterilization may not be very thorough or effectual. The milk, as ordinarily received, differs as to its exact condition from day to day, and hence varies in keeping qualities after having been subjected to prolonged heat. During the past year I have kept at least one bottle daily that has been sterilized at the Babies' Wards, and noted when it has spoiled. The following are taken from the records:

Sterilized.		Spoiled.	
1889—September	9th	September	29th.
"	15th	"	20th.
"	18th	October	25th.
1890—February	11th	April	11th.
"	22d	March	12th.
March	3d	April	12th.
"	22d	March	26th.
"	26th	April	3d.

I have copied these as showing occasional great variations, evidently caused by the different condition of the milk when received, as the same length of time is daily employed in sterilization and uniform care and cleanliness employed.

While the excellent effects of sterilization in the prevention of the decomposition of milk have been noted by all, the secondary effects of prolonged heat upon the ingredients of the milk do not seem to have attracted so much attention. This shows a danger of bacteriological study in overlooking factors that exist aside from microbes. Milk is a vital fluid, which may be affected by various influences, such as prolonged motion or oscillation, extreme heat, etc. It is upon the caseine especially,

[1] Read before the Medical Society of the County of New York, April 28, 1890

as this is the most offending substance to the infant's digestion, that the effects of great heat should be studied.

In the preparation of condensed milk excessive heat may swell up the albuminoids, and one of the methods of adulterating this article consists in thickening it by superheat, and hence being able to leave out a certain proportion of cream. It would hence seem possible that the continuous heat necessary for sterilization might toughen the curds, and hence render cow's milk more difficult to digest. Wishing to study this question I instituted a number of experiments, carefully comparing the character of the curds formed in sterilized and plain milk upon the addition of various reagents. In each case 10 c.c. of milk and 2 c.c. of the reagent were mixed together, and the effect noted first in the cold, and next upon warming over a water-bath.

Cow's Milk.

Reagent.		In the Cold.	In the Warm.
Dilute nitric acid.	Plain cow's milk.	Large curds, somewhat leathery, and lumping together.	Smaller curds, more separate.
	Sterilized cow's milk.	*Small* curds, not lumped together.	Same as in the cold.
Dilute sulphuric acid.	Plain cow's milk.	Curds similar to those formed by nitric acid.	Action same as nitric acid.
	Sterilized cow's milk.	Curds similar to those formed by nitric acid.	Action same as nitric acid.
Dilute lactic acid.	Plain cow's milk.	Soft lumpy curds.	Soft curds, more separate.
	Sterilized cow's milk.	*Small* curds, not lumpy.	Same as in the cold.
Dilute hydrochloric acid.	Plain cow's milk.	Large curds, confluent.	Smaller curds.
	Sterilized cow's milk.	Curds not large, but more confluent than with other acids.	Same as in the cold.
Artificial gastric juice.	Plain cow's milk.	Very soft curds.	Same as in the cold.
	Sterilized cow's milk.	No appreciable change.	Same as in the cold.
Bichloride of mercury, 1 to 16.	Plain cow's milk.	No appreciable change.	No appreciable change.
	Sterilized cow's milk.	No appreciable change.	A jelly-like coagulum of all the milk.

In glancing at this table it will be noticed that the addition of the various reagents produced larger and more confluent curds in plain milk than in sterilized milk, but the addition of heat in the former case, to a certain extent, broke up these large curds into smaller ones. The smaller separate curds of the sterilized milk did not, however, appear to be affected by warming. The continued heat to which the milk had been subjected in sterilization seemed to have produced all the change possible by this agent. The only exception to this was seen upon warming the sterilized milk to which the bichloride of mercury solution had been added, when, to my surprise, the apparently unchanged milk became transformed into a jelly-like coagulum.

Weaker solutions of the bichloride were then tried; 1 to 80 and 1 to 130, and found to produce no appreciable effect upon plain milk nor upon sterilized milk in the cold; but upon warming the latter firm clots were formed, varying in size according to the strength of the solution. A strength of 1 to 160 showed no appreciable change upon warming the sterilized milk. The prolonged heat necessary for sterilization evidently induced some alteration in the albuminoids that made them readily acted on by the mercury. An examination of the clot formed by the 1 to 80 solution, under the microscope, showed many fat globules entangled in masses of the albuminoids. As bichloride of mercury is not infrequently given in diarrhœa, it may be worth querying whether any such change would be produced in the body when sterilized milk is also administered. Wishing to see whether other antiseptics had any effect upon sterilized milk, I made tests with the following drugs: Naphthalin, 2½ per cent.; salicylate of soda, five per cent.; creasote (wood), five per cent.; boric acid (1 to 8), salol (saturated with sod. bicarb.), and found no appreciable change in plain or sterilized milk, in the cold or warm.

In order to compare the action of human milk with that of cow's milk under similar conditions, I procured a supply of the former and kept it for about eight hours, when part of it was sterilized. The following reagents were then added:

Human Milk.

Reagent.		In the Cold.	In the Warm.
Dilute lactic acid.	Plain human milk.	No appreciable change.	No appreciable change.
	Sterilized human milk.	No appreciable change.	No appreciable change.
Dilute hydrochloric acid.	Plain human milk.	No appreciable change.	No appreciable change.
	Sterilized human milk.	No appreciable change.	No appreciable change.
Artificial gastric juice.	Plain human milk.	No appreciable change.	Small soft curds.
	Sterilized human milk.	No appreciable change.	No appreciable change.

It is thus seen from these experiments, performed outside the body, that the prolonged heat necessary for sterilization has a tendency to make the caseine coagulate in smaller clots, but that there is still a very appreciable difference in the clot of cow's and human milk. The effect of sterilization upon the fat appears to be to collect it in rather larger globules. I have often noticed flakes of fat in nursing-bottles containing sterilized milk. Before administering the former it should be warmed and thoroughly shaken, in order to split up the fat as much as possible. Sterilization partially or completely coagulates the albumin, as shown by the following experiment: A portion of plain and sterilized milk was shaken with pure ether and allowed to stand, when it separated into three layers, the top being an ethereal solution of fat, the middle containing caseine, sugar of milk, and mucin, and the lowest layer holding the albumin. Examining the last layer under the microscope showed nothing in the case of plain milk, but amorphous masses of coagulated albumin in the sterilized milk.

I have tried a series of experiments upon dogs with gastric fistulæ, feeding them upon plain milk and sterilized milk, and withdrawing the contents of the stomach after an interval of ten minutes. The result of these trials was negative.

While sterilization is a great step in advance, it has by no means solved the question of infant feeding, as some seem to think. We still have to deal with a portion of indigestible caseine. In cases of diarrhœa the attenuation of this caseine by barley or wheat flour, clinically will often give good results. It is desirable to change as much of the starch into dextrin as possible before using these flours as attenuants. This may be accomplished by prolonged boiling in a tight bag. I have lately used the Arnold sterilizer and the double-boiler for the purpose of subjecting the flour to continuous heat at a high temperature. When the flour has been subjected to heat for a week, and a thin gruel made, and used to properly dilute the cow's milk, according to the age of the infant, an improvement in the character of the stools will often be noted. Where vomiting is present, the use of lime-water in large amount, as a diluent, is beneficial. I have used sterilized milk, thin gruel, and lime-water, one-third each, with a little sugar of milk and cream, with good results in many of these cases. Salt is always added to the bottle. At times it appears impossible for an infant to retain or digest milk in any form during an attack of diarrhœa. No matter how the milk is diluted or predigested, the irritable gastro-intestinal tract will not tolerate it. In such a case it is obviously best to stop milk completely for twenty-four or forty-eight hours. This was my treatment last summer at the Babies' Wards in diarrhœa with pronounced milk indigestion. During this interim nourishment was administered in the form of ex-

pressed beef-blood, with all traces of fat carefully removed, and diluted about five times with water, and the white of a fresh egg stirred in a cup of water, or cold barley-water. The importance of administering plenty of fluid in these cases is emphasized by the rapid shrinking of tissue in infantile diarrhœa. Particularly in hot weather a certain restriction in the administration of milk is often necessary. The heat causes a continual rapid evaporation from the skin, and, as a result of this fluid loss, the watery parts of the food are quickly absorbed to make up the deficiency. The thirst naturally produced by the heat causes the baby to wish to nurse or take the bottle very frequently, and when the watery part of the milk is taken up by the vessels, the thickened, solid part remains as a fruitful source of indigestion and diarrhœa. The free use of water, both internally and externally, will do much to ward off the summer diarrhœa of infancy. Stimulation in the shape of whiskey, administered in larger or smaller dose, according to the needs of the case, is recognized by all observers as a valuable therapeutic agent.

From the fact that masses of indigestible matter so frequently produce and keep up the diarrhœal condition, washing out of the stomach to rid that organ of the offending substances, and hence remove the source of irritation, although first advocated in Germany, has found many warm adherents in this country. The emphatic recommendation of the gentlemen employing and advising this procedure has led me to give it quite a considerable trial. The experience I have thus derived, which includes a summer at the Babies' Wards, leads me to the conclusion that stomach-washing, while very serviceable in a restricted number of cases, is by no means of such wide-reaching value or efficacy as would appear from the published reports. While accepting the good results of those who employ this procedure, it seems to me that equally beneficial results can be obtained, in the majority of cases, by milder measures. A broad division may be made of our cases into acute and chronic, the former including indigestion, ordinary summer diarrhœa, and cholera infantum, and the latter the persistent indigestion and malassimilation that are included in the term marasmus. In cases of acute indigestion and diarrhœa I have obtained fairly good results from stomach-washing, but in bottle-fed babies, where long continued malassimilation and atrophy are present, it has failed as signally as most other agents, in my hands. A glance at the theory underlying stomach-washing may aid us in deciding how far to apply it. As a rapid way to empty the stomach of undigested and irritating masses of food it is certainly effectual. It is a question, however, whether it has any advantages in this respect over the old-fashioned emetic. The offending substance in artificially fed infants is the caseine, which by coagulating in tough curds induces and keeps up a diarrhœa. Recognizing this fact, these curds are washed out of the stomach so that they cannot act as ferments upon the next supply of milk that is soon to be administered. But is not this beginning at the wrong therapeutic end? We are giving a food that the infant is unable to digest, and then, after a certain interval of time, pumping it out, before administering a fresh supply of the same kind of nourishment. In bottle-fed babies with diarrhœa the best results will often be obtained by stopping milk entirely for twenty-four or forty eight hours, during which time the expressed beef-blood and water and the egg-water may be administered, thus giving the irritated digestive organs an entire rest from grappling with the toughened curds of cow's milk, that are the source of most of the trouble. This would seem rational, and it certainly has proved in my hands as successful as keeping up the milk and washing out the curds. After the interval of rest, milk properly diluted may cautiously be commenced, taking care not to give it too frequently at the start. The necessity of stomach-washing may thus be obviated in a large proportion of the cases of acute milk indigestion and diarrhœa. In a certain number of cases of persistent vomiting, caused or accompanied by an undue amount of mucus in the stomach, a single stomach-washing will often stop the vomiting, and, with careful regulation of diet, the case will go on to recovery. The thorough cleansing of the stomach appears to give it a fresh start. When the caseine is not digested by the stomach, the hard curds will be passed in greater or less degree into the bowel, and continue here a fruitful source of trouble. On the same principle that the stomach is washed out, thorough irrigation of the bowel has been recommended for the removal of the irritating agent. But in the great majority of cases those natural emunctories, the intestinal glands, if mildly stimulated at the beginning of the attack, will accomplish all the washing out that is necessary. Hence the well-known efficacy of small doses of calomel, or the time-honored castor-oil given at the starting of diarrhœa, to hasten recovery. When the intestine has thus been emptied of offending masses, frequently all that is necessary is a most careful regulation of diet to prevent a continuance of the indigestion and diarrhœa. The strenuous advocates of stomach-washing and irrigation do not rest their case, however, upon the value of these proceedings in removing undigested and fermenting food alone, but also in cleansing the gastro-intestinal tract of various germs. We must hence glance at the bacteriological argument before completing our estimate of this therapeutic agency. While there is somewhat to commend stomach and intestinal irrigation from the point of view of undigested food, it seems to me the theory has a rather slender basis in regard to bacteria. That the mouth and pharynx harbor many bacteria is certain, and a large number are constantly ingested with the food. Most of these microbes are innocuous, or are rendered so when they reach the stomach, by the acid gastric juice.

Bacteria, we are taught, require an alkaline medium in which to develop. Even if the bacteria in the stomach were harmful, it would be exceedingly difficult to get rid of them by washing, as they collect in the folds of the mucous membrane and mouths of the follicles, and hence are difficult to entirely dislodge. To completely cleanse the stomach of them would require repeated washings and distention of that organ, which, according to theory, should be employed before each feeding, so that the incoming food need not be contaminated. But if it is thus difficult to cleanse the gastro-intestinal canal of ordinary bacteria, what shall we say of the utility of irrigation in the case of specific pathogenic germs that penetrate the mucous membrane, and hence are largely out of reach of washings? And yet stomach-washing has been strongly advised in the treatment of cholera infantum that is supposed to be due to the growth and development of germs in the intestinal mucous membrane. I have thus dwelt upon the subject of stomach-washing and irrigation, as they have suggested themselves to my thought and experience, because it has always seemed to me that heroic therapeutic proceedings should be avoided as much as possible in early life. If necessary, the most vigorous measures should fearlessly be employed by the physician, but if the same results can be attained by milder means, the latter are much to be preferred. A sledge-hammer will successfully drive in a tack, but so will a tack-hammer, with less general effort and disturbance. Stomach-washing is very disagreeable to the infant, and distressing to the mother, who can hardly be persuaded that her infant is not in danger of choking. Hence, as the same results can generally be attained in other ways, it is not often necessary to resort to it. The question may fairly be asked, whether any harm can come to the infant from washing out the stomach? As far as my own experience goes, I can answer this in the negative, with the exception of cases accompanied by much weakness or prostration. In the latter instance the passing in the tube and distending the stomach with water may provoke dangerous, if not fatal, syncope. One such accident happened to me, when a feeble infant, in an advanced stage of marasmus, suddenly died during stomach-washing. The

autopsy showed a flabby heart and stomach, and an atrophic condition of all the organs. My own judgment had been against stomach-washing in such a case, but as its safety had been strongly advocated, and its efficacy upheld in cases of marasmus, I felt like giving it a trial in these forlorn subjects. In some cases I have seen good results from injecting a quantity of starch-water, in which some subnitrate of bismuth has been rubbed up, well into the bowel. The infant is placed upon the left side, and from two to eight ounces slowly injected, according to its age and the tolerance of the bowel. In some cases a soft rubber catheter may be employed, in order to get the fluid a greater distance into the bowel. The object of this irrigation is to place a soothing, emollient fluid in contact with as much of the irritated or inflamed bowel as possible.

The greater attention that is paid to the hygienic and dietetic management of infantile diarrhœa, the less will be the need of purely medicinal treatment. Still very much good can be accomplished by a proper use of drugs. Some favor the so-called antiseptic method of treatment, which aims to check fermentation along the intestinal tract by the administration of antiseptic drugs. This is somewhat of a misnomer, since it is impossible to render the intestinal canal antiseptic. While good effects may be obtained by the use of these antiseptic agents, we must not lose sight of the fact that, as a rule, they are more or less irritating in character. Bichloride of mercury, salol, and naphthalin may be mentioned as types of this class. After giving them a trial, I have always returned to one drug, subnitrate of bismuth, that is worth more than all the others put together. While the bismuth may not be so strongly antiseptic, it more than makes up for this lack by being *soothing*. It is not absorbed, and, hence, can safely be given in large doses. The excessive irritation of the mucous membrane, a most important factor in keeping up a diarrhœa, is thus partially remedied. The addition of pepsin will assist in the further recovery, by aiding digestion.

The use of alkalies is theoretically indicated in many of these cases, and practically is attended by good results. The principal seat of catarrhal lesion in many cases of diarrhœa is the small intestine, which is congested and contains an undue amount of mucus, together with particles of undigested food. Moreover, this portion of the gut, that so urgently needs cleaning and attention, is entirely out of reach of washes, either by stomach or rectum. This being the case, we must aim to neutralize acidity and liquefy the mucus by the free administration of bicarbonate of soda or other alkalies, usually in combination with the bismuth. Some forms of subacute diarrhœa and indigestion are improved by the administration of small doses of dilute muriatic acid, which serves to aid digestion and tone up the mucous membrane. The bismuth and pepsin can be combined with the acid to form one prescription. It is not infrequently difficult in a given case of indigestion to tell whether an alkaline or acid mixture had better be administered. Sometimes the only way to make sure is to give both a trial; if one fails, the other may succeed. There appears to be somewhat of a reaction against the prescribing of opium in cases of infantile diarrhœa. Doubtless this has proceeded from an indiscriminate use of this powerful agent. If the bowels are locked up by an opiate, and still contain masses of undigested food, the results will be disastrous. Still there are cases in which a glandular irritation of the intestine persists after the bowel has been cleared and a proper diet substituted. The astringent and sedative effects of small doses of opium will be here very valuable. While it may not often be necessary to use opium, if other indications are carefully followed, this agent may yet be held in reserve and serve a useful purpose. In the severer forms of infantile diarrhœa the administration of alcohol, in the form of whiskey or brandy, is esteemed by all. By thus beginning early in the attack to steady the heart and revive the patient, the danger of spurious hydrocephalus later on will be reduced to a minimum. If there begin to be signs of drowsiness, with a weak heart, aromatic spirits of ammonia may be added to the free use of whiskey. In the brief sketch here offered no attempt has been made to go into the classification or pathology of diarrhœa, as this would open up too broad a subject. The object has been rather to outline the general plan and scope of treatment of cases that we are constantly seeing, for the purpose of evoking a free discussion and interchange of views. Among the careful observers and workers here assembled a discussion of different ideas and modes of treatment cannot fail to be of much value. To sum up, the following plan of treatment has commended itself to my judgment and experience: Careful sterilization of the milk, with proper dilution and attenuation. If, in spite of this, the milk will not digest, but continues to irritate, it is entirely stopped for a season and beef-blood or egg-water substituted. Stomach-washing is very rarely employed, but the gastro-intestinal tract cleared of indigestible masses at the beginning by small doses of calomel or other unirritating laxative. Occasionally the lower portion of the bowel is irrigated with bismuth and starch-water. The principal internal medication consists in the administration of large and frequent doses of bismuth, to which pepsin or other agents to aid digestion may be added. Stimulation by alcohol. In cases that tend to become chronic, in spite of properly regulated diet, the cautious administration of small doses of opium. In all cases a careful restriction of diet, but a free allowance of water.

27 West Fifty-first Street.

A STUDY OF THE HYGIENIC CONDITION OF OUR STREETS.

By CHARLES N. DOWD, M.D.,
NEW YORK.

During the last few months the making of subways for electric wires and the relaying of gas- and water-pipes have occasioned a very unusual upturning of the streets in this city. This has called forth many popular protests, many complaints that the upturning of so much earth, the liberating of so much bad-smelling gas, and the spreading of so much dust and dirt are injurious to public health. It is the purpose of this paper to discuss the true sanitary influence of this upturning of earth in the streets.

Is it really injurious to public health? If so, in what way does its influence act? There are two ways in which it may be supposed to be injurious:

I. By the liberating of disease-germs which were contained in the soil.

II. By the deleterious effect of disagreeable odors and of dust and dirt which do not contain disease-germs.

Let us consider these two ways in turn.

I. If disease germs exist in the soil they would be scattered with the dust which comes from the upturned soil as it dries, and so would have abundant access to the body. We must, therefore, study the bacterial content of the soil.

Ordinarily there are hundreds of thousands of bacteria in each cubic inch of soil at the surface. This number diminishes below the surface, so that at a depth of eight or ten feet there are hardly any. Just what the life-history of these forms is we do not know; many of them exist in the soil in the form of spores. When placed in nutrient gelatine they grow in great profusion. Most of them are probably harmless when introduced into the human body; but the bacilli of tetanus, typhoid fever, and cholera have been found in the soil.

In order to study these earth bacteria, small measured portions of earth are mixed in sterilized water so as to thoroughly disseminate the particles, nutrient gelatine is then poured over the mixture and the bacteria allowed to grow in it. A little colony of bacteria grows from each bacterium which is capable of developing in this gelatine.

To ascertain the number of bacteria which were in the specimen, we count the colonies.

To ascertain their characteristics, further cultivations must be made, the bacteria must be planted in various culture media and exposed at different temperatures, and they must be inoculated in different kinds of animals.

The labor of separating each variety and studying it thus in detail would be stupendous—it would be somewhat like going into a forest filled with unknown vegetation and attempting to describe all the peculiarities of each group of plants.

Hence bacterial earth examinations have largely been confined to the determination of the number of bacteria, not to the peculiar kinds.

In determining the significience of such examinations we must remember the following facts :

1. The number of bacteria does not necessarily indicate the number of disease-germs. Most of the disease-germs as yet discovered are bacteria, and the study of bacteria as a class bears on the subject of pathogenic bacteria; but pathogenic bacteria do not necessarily exist where the other ones do.

2. Small specimens of earth may show marked variations in the number of bacteria owing to minor local influences.

3. There may be certain bacteria which are injurious in the body but which do not grow in gelatine, and these, of course, would escape observation.

In order to gain data which apply to the especial soil under consideration I have made a series of comparative bacterial examinations. The ditches which give the strong odor of gas are the ones which the people most fear; they force themselves upon us by the very offensiveness of the odors which come from them and their suggestions of uncleanliness and disease. I have therefore compared sixteen specimens of gaseous-smelling earth from these ditches with sixteen similar specimens from ditches far removed from the gas mains, where there was no odor of gas. The conditions have been as nearly identical as possible in all respects excepting the presence of the gas. All the specimens were taken from new ditches and were examined immediately. The two specimens for each comparison were taken at about the same depth, usually twenty-four inches, and were taken on the same day, excepting in Nos. 15 and 16, where one day intervened between the taking of the gaseous and the non-gaseous earth.

The technique was based on that recommended by Fränkel[1] and Reimers.[2] In each test $\frac{1}{25}$ c.c. of earth was used. The work was done in the bacterial laboratory of the Alumni Association of the College of Physicians and Surgeons, New York City, with the strict precautions which are necessary in bacterial work. The studies were comparative, and the same technique, in all details, was used for the specimens compared, hence the liability to technical errors was reduced to the minimum.

The records of the earth examinations are given in the above table. All examinations were duplicated for control, but the duplicates corresponded so closely with the others that they are not inserted in the table.

In this table the variations in the individual results is very noticeable. Results of this kind must be expected in bacterial earth examinations, they may be due to differences which only extend through very small portions of earth.

The result of a single examination is therefore of little importance. We can only reason from the combined results of a large number of examinations.

The averages 37,243 and 39.873 are almost exactly the same, so that from these results we cannot argue that there is any difference in the number of bacteria in gaseous and non-gaseous earth.

I isolated and studied several species, but found them the same in gaseous and non-gaseous earth, excepting in one instance where I found the tetanus bacillus. It was found in non-gaseous earth, and was verified by being carried through six generations by inoculation in mice.

Effect of Passing Gas through Earth.—To further test the effect of illuminating gas on bacteria I made another series of experiments by passing it through earth in sterilized cotton-plugged glass tubes, and counting the bacteria before and afterward. To prevent the undue drying of the earth the gas was first passed through water which was slightly warmed.

The results of these tests may be tabulated as follows :

	Number of Experiments.							
	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Number of bacteria per c.c. before exposure to gas.	55,550	51,300	22,350	11,850	15,050	9,850	19,400	6,700
Number of days of exposure to gas.....	2	2	1	5	4	6	6	5
Number of bacteria per c.c. after exposure to gas.	19,985	33,050	162,300	5,400	7,788	12,825	70,700	32,705

As a further control of these results other specimens of the earth used for Nos. III., IV., and V. were examined after they had lain in cotton-plugged flasks in the laboratory, unexposed to gas, for three, five, and six days respectively; they gave 17,300, 10,500, 7,300 bacteria per c.c.—a diminution in every case.

If we now study these results we find that there was a diminution in the number of bacteria in one-half the cases and an increase in one-half. In one case, No. VIII., where this increase was especially great, the earth was very damp when put in the tube, and in general we think the conditions of heat and moisture had much influence.

There is no evidence that the gas had any influence on the bacteria in the earth in the tubes.

Effect of Gas-permeated Water on Typhoid Bacilli.—To still further test the action of gas on bacteria I made a third series of experiments by placing typhoid bacilli in gas-permeated water.

One-half pint of water was sterilized and gas from the city gas system was passed through it one month for series I., II., and III., and twenty-two days for series IV. The ingress of bacteria was prevented by sterilized cotton in the tubing. Mixtures of fresh growths of "bacillus typhosus" were then made in water, and their number determined by counting the growths from so much of the mixture as could be withdrawn by one dip of a given fine platinum wire-loop.

Similar quantities of the mixture were then put in the gas water, 2 c.c. for each. They were left there stated times, and then planted in gelatine and the growths counted. Duplicate estimations were made each time for control. The gas water was planted in gelatine and found to be sterile before it was used.

The results of the four series of observations may be tabulated thus :

Table showing the Effect of Gas-permeated Water on Typhoid Bacilli.

	Number of Experiments.			
	I.	II.	III.	IV.
Number of bacilli planted	68,280	21,120	10,420	13,600
Exposed to gaseous water, ½ hour	32,544	18,440	.....	3,280
" " " " 1 "	.....	.....	.....	1,896
" " " " 2 hours	.....	.....	300	21,212
" " " " 3 "	10,800	.....	.....	7,990
" " " " 4½ "	.....	212	.....	.....
" " " " 10½ "	.....	.....	.....	.....
" " " " 24 "	4,160	.....	2,820	848

This shows a diminution in bacteria under the action of the gaseous water, but the diminution is not much more marked than that shown in water itself in the tests made by Prudden,[1] M. Meade Bolton,[2] Wolffhügel and Reidel,[3] Straus and Dubarry.[4]

If we now compare the results of the three series of observations, we find that they give no reason for believing that the gas has a very marked effect on the bacteria in the soil. The number of observations is not large, and our only available methods of observation leave a large margin of variation; still, so far as they go, they lead us to think that the illuminating gas neither increases nor diminishes the number of bacteria to any marked degree.

Since we find no marked difference in the bacterial content of gaseous and non-gaseous earth, we must consider the effect of upturning the earth without reference to the gas.

So long as the soil is wet it cannot spread the bacteria in the air; but the soil does not long remain wet. It dries beside the ditches, it adheres to the implements, the clothes and boots of the workmen, to the planks and the wagons, and, in fact, to everything which comes in contact with the ditches; and, finally, much of it is left on the surface when the pavement is relaid.

In all these conditions it may be carried away as dust. The bacteria go with the dust, and access to the body is then made easy.

The amount of dust is certainly much increased by these ditches; but, on the other hand, the deeper layers of earth from which this dust comes do not contain nearly so many bacteria as the surface layer.

Grancher and De Champs,[5] in filtering water containing typhoid bacilli through the soil, found no bacilli lower than twenty inches.

[5] Recherches sur le Bacille typhique dans le Sol, Archives de Médecine expérimentale et d'Anatomie pathologique, January, 1889.

Observers have uniformly reported a marked diminution in the number of bacteria in the lower layers, and Reimers found that they were also less vigorous in growth.

Hence, although the ditches must increase the spread of bacteria, this increase cannot be as great as the increase in dust.

Whether they increase malarial disease we do not know, but there is very little malaria reported from people who live in New York. Moreover, it is believed that the organism which causes malaria belongs to a different class from those here considered, and other kinds of experiments would be necessary in studying them.

Conclusions Concerning Bacteria.—We think that the spread of disease-germs may be increased by this upturning of the streets, but we cannot think that this increase is very dangerous.

II. Let us now consider the second influence which these excavations may have, viz., the reducing the tone of the system by disagreeable odors, and by the spread of dust and dirt not containing disease-germs.

The subject of hygienic surroundings is no less important because it is indefinite. No one will deny that the air is more invigorating and wholesome in a well-selected spot in the Adirondacks than in the crowded streets of the lower part of our city. The crowding of the people together, and the consequent insufficiency of oxygen, the contaminating of the air from the odor of cooking, the tenement-house filth and garbage, and the general uncleanliness, all have their unwholesome effect. They do not necessarily produce active disease, but they debilitate the system. Hun[1] has recorded and referred to numerous cases where headache, digestive disturbance, and debility followed exposure to air contaminated from leaky sewers. Both reason and experience teach us to expect such a result. Now the filling the air with the odor of a gaseous ditch is certainly another element in the unwholesomeness of the city. If our houses and places of business were exposed to it for long periods it would be a very serious matter. When we see, for instance, the difference in the course of summer diarrhœa of children here and in the country, we feel that there is good reason for taking all possible precautions against every element which adds to the unwholesomeness of the city. A child who has been debilitated by bad hygienic surroundings has less vigor to resist summer diarrhœa than a child of equally good constitution who has not been so debilitated; if he must remain in these surroundings while suffering from the disease it is still worse. A man whose resisting power is unimpaired can grapple better with any exhausting disease than one who has been debilitated; the severe course of pneumonia in drunkards illustrates this. There are also results of animal experiments which bear on the question.

Charrin and Roger[2] inoculated with attenuated anthrax virus 8 white rats which had been thoroughly fatigued by running in a rotating cage seven hours a day for four days. They also inoculated 4 rats in a normal condition. Seven of the tired animals died of anthrax, while all the others survived.

Trudeau[3] inoculated 10 rabbits with tubercle bacilli; 5 of them he turned loose on an island where they were in the open air and were well fed; 5 he put in a box in a dark cellar and studied them in the amount of food given. At the end of four months four of the rabbits which had been in the open air were killed; they showed no signs of tuberculosis but were remarkably fat and muscular. The fifth one died of tuberculosis one month after inoculation. Four of those in the cellar died of tuberculosis within three months; the fifth was killed after four months, he had far advanced tuberculosis.

[2] Revue Scientifique, quoted in Boston Medical and Surgical Journal, May 8, 1890.

[3] Environment in its Relation to the Progress of Bacterial Invasion in Tuberculosis, Transactions of the American Climatological Association, Philadelphia, 1887.

These experiments certainly show that the condition and surroundings of animals have an influence on their power of resisting disease. Clinical experience teaches us the same in regard to men. We should, therefore, take all due precaution to shut out debilitating influences. No one of us would wish to have a ditch dug in front of his office, which would fill it with the odor of gas-permeated earth for even a few days; not that it would bring on an attack of typhoid fever or diphtheria or any other severe disease, but it might cause malaise or digestive disturbance of such severity as to add one more element to those which lessen the resisting power of the system, and we may need all our resisting power at any time to throw off disease to which we have been exposed or to carry us through an exhausting illness.

We cannot take the position of alarmists in this matter. We do not expect that ditches in the street will cause an epidemic of any kind. We do, however, believe that the upturning of the streets increases in a moderate degree the liability to disease, both by the spreading of bacteria and by otherwise producing bad sanitary surroundings.

Mr. Stetson tells us, in the May *Scribner's*, that a "safe, clean, and smooth roadway and sidewalk is the right of every citizen." On sanitary grounds we have a right to claim from the city authorities that much care should be taken about allowing the streets to be upturned.

MULTIPLE ARSENICAL NEURITIS, WITH REPORT OF A CASE.

By HENRY S. STARK, A.B., M.D.,

NEW YORK.

I AM desirous of placing this case on record, from the comparative infrequency of this particular variety of polyneuritis and the scarcity in medical literature of authenticated cases of a similar origin, and, secondly, because there is a belief among certain careful observers that the nervous symptoms following the ingestion of toxic doses of arsenic vary very materially in intensity, extent, and permanency, according to whether the poisoning has been sudden or gradual.

The fact that the exact pathology of this peripheral nerve lesion has only been ascertained within the last decade seems to offer a satisfactory explanation for our former inability to establish the relation of cause and effect between the different sets of nervous phenomena following the ingestion of poisons. While it is almost ancient history that paralysis, ataxia, sensory and trophic disturbances may follow the absorption of irritant poisons, it is only within a few years that these symptoms in certain cases have been attributed to lesions of the peripheral nerves.

I do not, however, intend to convey the idea that all cases of arsenical paralysis are peripheral in their nature, for there have been reported a number of cases by reliable authors which make it certain, judging from the clinical histories, that these paralyses may possibly owe their origin to anatomical changes in the central nervous apparatus. This conclusion cannot, unfortunately, be fortified by post-mortem examinations of the cord, for I learn, after a careful review of the current literature, that there are no autopsies on record; there are, however, on record a few autopsies which confirm the theory of a peripheral neuritis. Among contemporaneous writers who have reported cases of arsenical paralysis due to a myelitis are, Seguin [1] with three cases, Da Costa [2] with one, Mills [3] with one. It is, however, noteworthy that ever since multiple neuritis became recognized as a distinct affection, the number of cases of spinal origin has markedly diminished, while the tendency to-day is to regard these cases as of peripheral origin. Granting, then, or rather, assuming that paralysis due to toxic agencies may be peripheral or central in nature, it appears difficult to decide, owing to insufficient data, what factors determine whether the poison will affect the one or the other lesion. In the case of arsenic, clinical evidence has demonstrated that this idiosyncrasy does not depend upon whether the poisoning has been acute or chronic, or whether the poison enters the system by inhalation or ingestion.

In determining whether the paralysis following the use of arsenic is due to a spinal or a neural lesion, the clinical picture furnishes grounds for a presumptive diagnosis. A peripheral neuritis is highly probable if the onset of the trouble has been rapid and has been attended by fever and other manifestations of an acute inflammatory disease; if the sensory disturbances are more prominent, and earlier present than the motor; if the sensory and motor phenomena are localized to single symmetrical nerves or confined to sets of symmetrical nerves; if there is present a tenderness, elicited by finger pressure, along the course of the affected nerves or paralyzed muscles; if there is an area of anæsthesia corresponding to the region of distribution of the inflamed nerve or nerves. Additional information which speaks for a neuritis is the cheiropodal species of paralysis, the fact that the bladder and sexual organs are not involved, the immunity from bed-sores, the occasional presence of a complicating *neuritis optica*, and certain peculiar trophic symptoms, such as œdema, glossy skin, excessive perspiration of the affected limbs; finally, a tendency to recovery. A converse picture of the above, not necessarily in all but in several of its aspects, would arouse a strong suspicion of a myelitis.

The close analogy of the two forms of toxic paralysis suggests another problem, which still awaits solution, namely, is the integrity of the spinal cord and of the peripheral nerves ever simultaneously disturbed, or does a peripheric lesion tend to produce a central one, and *vice versa*. This would be a legitimate inference, although there is again no post-mortem evidence extant to confirm this hypothesis. There are those who believe that the nerve lesion may spread to the cord, and produce a typical myelitis. Among these are Leyden and Strümpel. There are others, as Pitres and Vaillard,[1] who conclude that the neural lesion plays no part whatever in the production of the clinical picture, but that the specific symptoms depend upon structural changes in the cord and posterior nerve-roots.

There are thus a number of interesting questions connected with the study of toxic paralyses, about which our literature is very elementary and our knowledge only conjectural. In this connection the following quotation from Seguin [2] is very pertinent: "The physician, who, meeting with a case of arsenical paralysis, would seek for information on the subject . . . would be grievously disappointed. Such writers as Grasset, Ross, Wilks, Bauduy, Hamilton, and Hammond, do not mention the affection at all, while Rosenthal devotes only a short paragraph to arsenical nervous symptoms." In view of this sentiment, I think no apology is necessary for the publication of my case.

Miss H——, aged eighteen, Hungarian by birth, states that, one night, in a fit of despondency, she swallowed a large quantity of Paris green with suicidal intent and then retired. Thereupon she began to vomit profusely and thus rid herself of much of the poison a physician being now summoned prescribed antidotes and emollient drinks. She was soon seized with agonizing pains in the region of her stomach, and these rapidly radiated over the entire abdomen. On the next morning she had a slight chill, followed by a sense of heat and accompanied with considerable prostration. The violent vomiting now ceased, but the burning pains within the abdomen became aggravated to such a degree that it was necessary to keep

her moderately under the influence of narcotics. In this condition she remained for about ten days, when she became aware that her vision was growing indistinct and her hearing defective; the white of the eyes was not reddened but the lids were somewhat swollen; at about this time also an eruption of "red pimples" made its appearance over the forehead, around the lips, and also in the right intercostal region. Within a few days these latter symptoms disappeared, leaving her with her normal vision and hearing. Her recovery from the immediate effects of the poison was now assured, but for a long time a considerable degree of gastro-intestinal irritability persisted. At about this time, some twelve days after taking the poison, she complained of pains of a darting character in her legs, feet, forearms, and hands. These pains were intermittent, coming and going at short intervals, and so intensified at night that her sleep was much disturbed; they began simultaneously in all the extremities. Accompanying these were feelings of numbness, coldness, and formication, the last especially marked in the fingers and toes. At this time also her hands and feet were constantly bathed in cold perspiration and began to swell. Whether these symptoms were preceded by, or attended with, fever cannot be determined. She became very sensitive to pain, the slightest pressure caused her to cry aloud, even the pressure of the bedding caused her uneasiness. The severity of these sensory disturbances gradually abating, she concluded on the third week after swallowing the arsenic to get out of bed; she was assisted on her feet, only to learn that she was unable to support herself, and that motion in her hands was seriously impaired. At this stage of her illness she first came under my observation.

Status Præsens.—Her previous history is unimportant, while there are no antecedents in her family history to which we could attribute her present affliction.

General Inspection.—Patient is confined to bed and looks anæmic. She has the characteristic wrist-drop and foot-drop. Atrophy of the muscles of the radial, posterior brachial, anterior tibio-fibular, and peroneal regions is marked, the interossei of the feet and hands are somewhat atrophied, so that in the latter the thenar and hypothenar eminences are rendered very prominent. No other muscles of the body appear to be involved. There are slight tremors of the calf muscles, while there are fibrillary twitchings of individual parts of several of the atrophied muscles, notably the palmar interossei; in other muscles twitchings may be elicited on tapping them gently with the fingers. There is nothing in the gross appearances of the sensory organs to indicate past or present disease.

Reflexes.—On testing the reflexes it was learned that the superficial, *e.g.*, plantar and abdominal, responded sluggishly, and the deep, *e.g.*, patella-tendon and the ankle-clonus, were absent; the organic reflexes, *e.g.*, bladder, rectum, and pupillary, gave no evidences of disturbance.

Sensory Disturbances.—Patient still complains of burning pains shooting along the extremities below the elbows and knees. The tingling sensations in the hands and feet are a source of great annoyance, and these, in connection with the pains, rob her of her sleep. The disturbances of sensibility are of the nature of a cutaneous hyperæsthesia rather than of an anæsthesia. Tenderness along the course of the affected muscles is easily elicited, it renders the examination painful and interferes much with the treatment by electricity. Firm pressure on the muscles at the points of exit of nerves is particularly painful. There is a slight patch of anæsthesia to be detected on the dorsum of the feet, extending upward as far as the ankles, and on pricking the integument over the posterior aspects of the hands with a pin, delayed transmission of painful sensations is also to be detected.

Motor Disturbances.—The motions of flexion and extension at the elbows and knees are not impaired, but below these there is such a general loss of strength and power that the several groups of muscles have eventually lost their normal equilibrium. Patient can raise her hands to a very limited degree, showing that the paralysis is not complete; her feet have fallen forward from their own weight. Being asked to raise the latter, she makes an unsuccessful attempt, nevertheless it can be noticed that she is slowly regaining this lost power. Voluntary extension of the toes and phalanges is very imperfect.

There are no Tendon Contractures.—On applying the electrodes of a faradic battery over the motor points on the extensor aspect of the forearm and the outer aspect of the leg—the sides presumed to be involved—electric contractility of the muscles supplied by the musculospiral and anterior tibial nerves is observed to be abolished; these nerves and their branches respond, however, to a galvanic current of average strength.

Her pulse, respiration, and temperature are normal, and examination of the urine is negative. Appetite fairly good, bowels constipated. The bladder and rectum were never affected. She remained under my observation for about two weeks. During this interval treatment consisted in daily applications of a galvanic current, systematic massage, the extremities were enveloped in cotton, and she was put upon fairly large doses of iodide of potash and strychnine, the former to free the system of the poison, the latter as a nervine. The patient was then transferred to the Mount Sinai Hospital, into the service of Dr. E. G. Janeway, who confirmed the diagnosis. Here she remained some six weeks, when she was discharged, cured. She then presented herself at my office, when I found that she could again use her hands and feet for all purposes, but she states that she feels very weak on her feet, and that the integument is constantly cold. At the hospital the R. D. was tested and found, the examination of the eyes gave negative results.

This clinical picture, taken as a whole, undoubtedly indicates that we were dealing with a nerve lesion in contradistinction to a spinal one, and further, that the nerves involved were not affected throughout their entire lengths but only in their distal extremities; it appears also that the sensory as well as the motor fibres were involved. The fact that the skin and tendon reflexes were practically abolished and the prominence of the trophic symptoms seemed to speak for an interruption in the communication of individual nerve fibres from their centres of nutrition or "trophic centres;" conversely, the fact that the organic reflexes were undisturbed while rectal and bladder symptoms were conspicuously absent seemed to disprove the idea of a myelitis.

This and parallel cases make it almost safe to conclude that toxic agencies, such as arsenic, lead, mercury, carbonic-oxide gas, tobacco, alcohol and the poisons of the infectious diseases, when they exert their toxicity on the nervous system, exhibit a selective action on the peripheral nerves. Thus the lead paralyses, the functional amblyopia of tobacco, alcohol, and medicinal agents, and certain species of ocular paralyses and neuritis can probably be attributed to peripheral lesions.

270 East Seventh Street.

St. John's Guild.—The trips of the floating hospital of this association will commence early in July, and the sea-side hospital will be opened at the same time. Last summer 30,057 sick children and mothers were taken on the floating hospital, the cost being but twenty-one and one-fourth cents per person. There were 1,573 who received hospital care and treatment at the sea-side hospital at New Dorp, S. I.

St. Mary's Hospital, in East St. Louis, was dedicated on June 1st, by Bishop Janssen. Although this town is a large railroad centre it has never had a hospital, and the injured or sick railroad employees had to be taken to St. Louis, or to the County Hospital at Belleville, fourteen miles away.

Clinical Department.

FIBRO-MYOMA OF UTERUS—SLOUGHING—RECOVERY.

By WILLIAM S. CHEESMAN, M.D.,

AUBURN, N. Y.

Mrs. S——, forty-nine years of age, and mother of three grown children, had suffered from a uterine fibroid for five years, to my knowledge. This had been first discovered by a physician some two years previously, or seven years ago. This tumor filled the abdomen to a finger's breadth above the umbilicus and caused much cystic irritation, pain on walking, and menorrhagia. The patient was considerably depleted by monthly losses, but being of an energetic spirit refused to lie up for treatment, and finally passed out of my hands.

On June 23, 1889, in the absence of the physician who had been attending her, I was called to see her again. She had flowed excessively for nine days, and was blanched and delirious, but without fever. The bleeding had ceased spontaneously. Restorative treatment was pushed, but the anæmia delirium continued for some five weeks, of which period she now retains no recollection whatever. Digital examinations made from time to time with the greatest gentleness, on account of sensitiveness of the uterus, revealed no change in the tumor, which bulged upward as high and large as ever. Fortunately there was no return of hemorrhage, and the patient's strength slowly returned till she was able to sit up. On August 14, 1889, in accordance with her earnest desire, she was taken to Lake Ontario for change of air. She was moved in a bed, and stood the short journey well. During an absence of nearly two months she menstruated once, but the flow was not excessive.

On her return (October 2, 1889) she was admitted to the Auburn City Hospital, improved in strength, but bedridden. Before her trip she had seemed too weak to warrant local treatment, or even thorough examination. But I was now able to investigate more carefully. The uterus was still very sensitive, and there was considerable leucorrhœa. A probe entered the uterine cavity to a depth of nearly five and a half inches, being deflected to the patient's left. The tumor seemed to occupy the fundus and right-hand wall. No pedunculation could be demonstrated; nevertheless, I determined to be certain on this point, and arranged to dilate the cervix under ether, explore the cavity, and remove the growth, if this were possible. At this juncture, however, the patient was seized with hemorrhage—the first since June. This was controlled by the vaginal tamponade, but not before enough blood had been lost distinctly to lessen her strength.

After this last bleeding the temperature began to rise, and the vaginal discharge, which had never been more than a free leucorrhœa, became abundant and decidedly offensive. The patient was about this time transferred to her own home. Here the gravity of her condition steadily increased, her fever reaching 103° or 104° F., afternoons, and the discharge, in spite of antiseptic douches, becoming more abundant and malodorous. I now felt sure that, in consequence of the patient's lowered vitality, the tumor had perished, and was slowly sloughing. In the hope of assisting in its extrusion I administered fld. extr. ergot tentatively, in half-drachm doses, every two hours. The uterus reacted promptly and with such vigor that morphia had to be used to allay the colic; but with the unexpected result that the discharge ceased, and the patient had a chill followed by a rise to 105° F. The next day a mass about as large as a Seckel pear was expelled. Notwithstanding this latter encouraging result, it was some days before I dared repeat the ergot; and when I did, the same colic, stoppage of discharge, chill, and high temperature ensued, but without any subsequent extrusion of slough to compensate for the disturbance. Evidently the uterine wall, under the influence of the ergot, shut down upon the growth so tightly that discharges were retained, a septic chill, etc., ensuing. I therefore ordered ergot in three doses, of from ten to fifteen drops, two hours apart. This worked well. Ensuing pain was not severe, discharge, though lessened, did not cease, and no chill resulted. From day to day this treatment was followed, fragments and shreds appearing in the fetid pus which poured from the uterus.

All this time I was uncertain whether the growth were pedunculated, or encapsulated, or partly both. The phenomena following full doses of ergot seemed to argue that the mass must still, in whole or part, be within the uterine substance. Nevertheless, it seemed clearly proper to dilate the cervix, explore, and, if possible, remove the necrosing tumor. Accordingly, on November 25, 1889, ether was administered, and with the assistance of Drs. Parker and Jenkins, I dilated the cervical canal with Barnes's and other rubber dilators, until two fingers could readily enter the body of the uterus. The situation of affairs was then immediately made plain. The cavity of the uterus was enlarged, and not perceptibly encroached on by the tumor. While the body of the womb was pressed downward by one hand on the abdomen, the finger carried to the fundus detected an opening in the roof of the chamber, circular in outline, about as large as a fifty-cent piece, and which felt extremely like the dilating os of a parturient womb. Within this circular rim, between the body of the tumor and the uterine wall, the finger-tip swept around, unobstructed separation between the uterus and tumor having occurred to this extent. But beyond this the finger could not penetrate. No signs of further separation, or even demarcation, between the growth and the womb could be made out. The free surface of the growth was rough and uneven.

The question now was whether to proceed with the dilatation, and attempt to enucleate this necrosing, but still firmly attached, mass. My reading had not given me a very pleasant impression of the results of such attempts, even when made by the most skilled operators. My patient was in a very precarious condition, weak from previous bleedings, and further exhausted by septic absorption and fever. It did not seem to me, nor to my colleagues, that she could bear an operation which must be prolonged, and which probably would be bloody. If any hazardous attempt were to be made, supra vaginal hysterectomy appeared preferable to a slow intra-uterine enucleation. Furthermore, as the tumor was sloughing, and there was free egress for sloughs, it seemed likely that nature herself might be able to deal with the case. Accordingly, after curetting away all loose fragments, and washing out the cavity with a bichloride solution, I stopped the ether.

Recovery from this exploration was uneventful, except for a sharp chill, to which no special significance seemed to attach. The dilatation secured freer drainage, and the daily extrusion of small particles under use of ergot went on. Nevertheless the situation grew graver. In spite of alimentation, tonics, and stimulants, vaginal and intra-uterine antiseptic douches, and of attempts to control temperatures by antifebrin, the patient perceptibly lost ground. I several times planned to etherize and dilate again, in hope of finding the mass softened and easy of removal, but fearing the consequences of even slight shock to a much-weakened patient, refrained. Altogether I felt myself in that unpleasant predicament picturesquely located by seafaring men, "between the devil and the deep sea."

One day late in December (the 27th), however, there was passed into the vagina a large, ragged, and intensely fetid slough, which I removed. About two days later a similar fragment came away. After the passage of this latter the temperature rapidly subsided, reaching 98⅘° F. in a couple of days, and never rose again. The discharge gradually lessened, and its odor disappeared. With the cessation of sepsis the patient began to improve, and in about a month was able to sit up, and even walk a little.

An examination made late in January, 1890, showed

the uterus natural in size, light, movable, free from tenderness, and without trace of the tumor which had formerly filled the lower abdomen. The patient is now able to attend to her usual duties, and the constitutional traces of her long illness have almost disappeared.

Here, then, apparently, we have the record of a surgical triumph on the part of nature, and a further illustration of the point recently emphasized in these columns, that assistants to this antiquated, but not always bungling operator, do well occasionally to hold their hands.

ALCOHOLIC DELIRIUM IN PNEUMONIA.

By GEORGE T. WELCH, M.D.,

PASSAIC, N. J.

Juergensen has argued that the high temperature in pneumonia is answerable for the active delirium which is sometimes found in that disease. I have observed in my own experience that, in some cases where the temperature has not risen above 103° F., if the patient has been a victim of alcoholism, destructive nervous symptoms have been evoked, which have not abated even when, under the influence of antipyretics, the bodily heat has fallen $3\frac{5}{10}°$. This author states, however, that "the frequency with which one meets this form of cerebral symptoms will depend upon the extent of dram-drinking in the neighborhood." He found it common in Kiel, and not at all in Tübingen, while in Sweden nearly seven per cent. of all cases of pneumonia suffer from it. Grisolle regarded alcoholism as the most frequent cause of delirium in pneumonia. And Huss, from his observation of the frequency of this nervous disturbance in the pneumonia of drunkards, was led to describe a special form of the disease as *Pneumonia Potatorum*.

It does not at all follow that a man must have been a drunkard, in the common meaning of that term, but even if he has been but a steady moderate drinker it is not improbable that, under the stimulus of fever in pneumonia, at a time when the blood is but imperfectly oxygenated, the nervous system will become maddened and produce paroxysms as wild and intense as those of insanity. Chronic alcoholism has produced already lesions, or, at the least, disturbances of nervous functions, which leave the system ripe for riot. Nor is it a necessary factor that the temperature should be high which flares the torch to awaken this bacchanal. Delirium tremens may stagger forth with ramp and fury, like Cassio in the drinking scene, but the sinister, cool, sneering Iago has laid the train which tosses him into passion. Orgies, hunger, hardships, watching, may be the cause of the outbreak. So, too, in the pneumonia of an alcoholic. I have known a temperature of but little above 100° to produce tremors, hallucinations, and ferocious violence.

Habitual alcohol-drinkers are far more liable to pneumonia than others (Wilson). The vitality is lowered, and the system susceptible to extraneous influences to an immoderate degree. Probably this was at one time better understood than it is at present, for, in spite of prohibition warnings, I think it is indisputable that there is less of drunkenness now than in the past. The three-bottle men are under the table, not to arise again, and some of the younger men in the profession may not have seen a case of delirium tremens at all. Certainly it was not an uncommon affection even as late as twenty years ago. In the first year of my practice I saw two cases—this was in 1869, but for several years I had not seen a case, until this winter, when I have met with two more.

But I have from time to time seen here and there a case of alcoholic delirium in pneumonia which would have puzzled me had I not known how to associate the tremor and the bizarre imaginings of the patient with the true cause.

In a recent case a stout young workman, a moderate drinker, whom I had known in health for his jaunty demeanor, on the third day of an attack of pneumonia of the lower lobe of the right lung, after remaining awake for thirty hours, began to exhibit the most curious interest in all that was said or done at his bedside. He would raise his head from the pillow, and follow with piercing eyes each motion of his attendants, and start with an intense look at the rustling of the bedclothes, or slight creaking of his mattress as he moved himself wearily in bed. On the succeeding day I found him in his night-clothes parading the dining-room, a fixed sardonic smile glazing his features and a glare of madness in his eyes. His wife and an attendant were hanging at his arms, vainly persuading him to return to his bed, while with suppressed passion he strode unmindful. Sternly demanding that he should go to his room, I prevailed over his humor, and taking his temperature in the axilla, I found it had fallen from 103° to 101° F., and exploration of the chest revealed the fact that the pneumonia had abated considerably since the night before. A slight tremor was apparent, and the patient insisted that his food had been drugged, and stoutly asserted that he would take no more medicines; but this he would do when I presented them, while he would spurn them violently from the hands of others. He got out of bed suddenly and began to fumble on the floor, muttering that some of his tools had been knocked down in the shavings and would be lost. When I saw him in the afternoon he was dressed, lying prone on the bed, at full length, slippers and smoking cap on, and a lighted pipe between his teeth, puffing vigorously. He hailed me hilariously, and wanted to know when we were going to take his measure. His eyes were glittering, and his demeanor was reckless. He gulped down his anodynes and mixtures with a mad haste, starting involuntarily now and then. He felt no pain, but struck his chest a remorseless blow to confirm his words. He lost all decency, expectorating on his bed, and vilifying his attendants. A few hours later, on my return, I found his bedroom stripped of all furniture but his bed. He had developed a destructive tendency, and with difficulty had been restrained from demolishing pictures, chairs, and household goods. His strength was prodigious, and like the Homeric simile of the wild boar making his savage, sturdy passage through the brambles with half the hunters' pack hanging at his sides, our iconoclast made his way from room to room with half a dozen of his neighbors barring and opposing him in vain.

I had been giving him small doses of chloral and the tincture of digitalis without avail, but I now changed my tactics, and from thenceforward, for twelve hours, gave him hourly fifteen grains of chloral and half an ounce of the infusion of digitalis, until his obstinate vigilance was broken and he fell asleep. Afterward the delirium was less manifested, and finally it departed, the patient making a good recovery.

In a case under my care at Keyport, where I formerly practised, the delirium took on a grotesque form, the patient chattering and laughing, a procession of ludicrous figures, the eccentric of the town, aptly hit off by a descriptive phrase, came trooping in at a second-story window and passed over the bed and through the wall. The magician lay convulsed, coughing, colliquative, laughing, shouting, and wildly furious by turns. He heard voices, was fearful of being poisoned, and was mirthful and wretched, all in the chimes of a quarter of an hour. But the humorous element predominated. As in the other case, the symptoms yielded to chloral and the infusion of digitalis, as did another case where the symptoms took on the convulsive form, the patient roaring in his contortions, while he fought like a demon.

And here I shall take occasion to insist upon the free use of these two remedies, boldly and confidently administered. Opium and its derivatives, and a long list of narcotics and anodynes are useless, they are ineffectual darts thrown upon the panoply of the dragon; but chloral and digitalis—either good, but combined irresistible—will certainly triumph if used heroically. A series of cases of

delirium tremens was reported by me in 1875, and published in the "Transactions of the New Jersey Medical Society," in which, after losing time with other measures, I gave tincture of digitalis, in half-ounce doses, until the symptoms abated, and sleep supervened after from one and one-half to three ounces had been given. No ill effect followed, and the same disease occurring in one of the patients a few months afterward, I began the tincture of digitalis in teaspoonful doses at once, and conquered the delirium in a few hours. These cases remained under my notice for some time afterward, and I made frequent examinations of the heart to detect any accumulative action of the drug, but did not discover any.

Although digitalis is among the most powerful of cardiac poisons, it rarely proves fatal (Von Boeck), and, as Stillé observes, there would appear to be something in delirium tremens which insures a singular toleration of this medicine. Digitalis, in small doses, is a spur to a feeble heart, driving it down to the death, if long continued, and it is not until comparatively large doses are given that we get the cardiac tonic properties promised by therapeutists. In the use of a remedy capable of great results we must be both bold and wary. To be only the latter, is to become subject to the echoes of disaster which every physician has heard and few have witnessed.

Chloral alone has answered the indications in alcoholic delirium, but in small doses it seems to have little effect unless very frequently repeated, and in large doses there is danger of heart-paralysis, but combined with digitalis each may be given in moderate doses, and yet a speedy effect be evinced.

A case of pure delirium tremens might yield in time to other and simpler measures, the probabilities are that it would; but associated with pneumonia the condition is hourly increasing in gravity, and only a short time is offered in which to do our utmost to rescue the patient from impending death. Brought face to face with this situation I have thrown aside all other means, and have scored success with the combination I so confidently recommend.

THE PREVENTION OF THE TOXIC EFFECT OF COCAINE.

By ISIDOR GLUCK, M.D.,

OCULIST AND AURIST TO THE ACADEMY OF THE SACRED HEART AND BROWNELL HALL, OMAHA, NEB.

Cocaine, our most useful local anæsthetic, has one great disadvantage which anyone who has much employed the drug must have experienced, viz., its toxic effect. Sooner or later, in the experience of everyone, this is manifested, and generally when least expected. In my own practice, using the drug frequently in diseases of the eye, ear, nose, and throat, and seeing at times most alarming effects, I came to have a certain dread of it. Though cases are reported I have never seen it produce the toxic effect as a result of its use upon the eye. Its failure to do so is probably because absorption through the cornea is much slower than elsewhere, and I have always made it a rule to guard the tear-ducts—the channels leading to the nose and throat. In operations on the cornea I have always made it a rule to use the drug in the powdered form, the moisture of the eye is thus absorbed, and as the process of solution is slow, the anæsthesia is correspondingly prolonged. It is in the treatment of the nose and throat, and when used hypodermically, that cocaine produces most alarming symptoms. Though used in strengths varying from four per cent. to twenty per cent., sometimes the weakest solutions will produce the toxic effect in one susceptible. There is a great difference in individuals in this respect, some being very susceptible, others scarcely so at all. Patients with neurotic tendencies are generally more susceptible than others.

The first symptoms marking the toxic effect of cocaine are restlessness and pallor of the face. In some cases perspiration appears about the mouth and on the forehead, and patients invariably express themselves as feeling "very peculiarly." In such cases, treated daily, there is restlessness at night.

Miss H. M——, blonde, aged twenty-four, suffering from hay fever. Applied a four per cent. solution of cocaine to left nostril, had hardly removed the cotton-carrier when she sprang from the chair exclaiming, "Doctor I cannot breathe; I am choking." In a few minutes all effects had disappeared. Next day I applied a one per cent. solution of sulphate of atropia; in a few minutes patient complained of a feeling of lassitude, pupils normal, no flushing of the face or dryness of the throat. The same patient, fifteen minutes after a dose of fifteen grains antipyrine, manifested the following symptoms: Face puffed, pupils dilated, eyelids swollen, conjunctiva injected, rash all over the body, pulse scarcely perceptible at the wrist, breathing hard and rapid. I have had other cases susceptible to cocaine and atropine, and others, like the one just mentioned, susceptible to the influences of cocaine, atropia, and antipyrine. All have been blondes with neurotic tendencies, and generally adults of middle life. Children seem to bear cocaine well, as they do atropine. Aside from the alarm and inconvenience of the toxic effect of cocaine, the drug has another peculiarity in solution. It does not remain stable. After twenty-four hours it loses its anæsthetic properties to a greater or less degree, and in a few days becomes useless. The strength of the solution varying thus it has to be freshly made every day.

For the reasons above mentioned I was led into a series of experiments with a view to rid cocaine of these defects, the result being the discovery that cocaine in combination with phenol not only removes the objectionable features, but increases its usefulness. The formula which I have adopted is the following:

℞. Phenol	gtt. ij.
Aqua destillata	ʒ j.

Shake until solution is perfect, then add cocaine hydrochlorate, gr. x.

I have been using the above formula for over a year, and since using it have never had to deal with the toxic effect of the drug. In fact I have been able to use it in any quantity, and in any part of the nose or throat, without the least fear of harmful consequences. Phenol, in the same manner as cocaine, by suspending the functions of the sensory nerves, is itself a local anæsthetic of no mean power. The combined action intensifies the anæsthetic. Phenol also coagulates albumin and combines with fats, forming a very superficial eschar which prevents the absorption of cocaine, and hence its toxic effect. Phenol is also destructive of bacteria, fungi, etc., and prevents decomposition in the solution. Its effect is also to ward off the congestive and other reactive effects experienced after the use of cocaine, which, next to chloroform and opium, is nature's greatest boon to mankind.

Résumé: The Advantages of Phenol and Cocaine.—1, Prevents toxic effects; 2, increases the anæsthetic effect; 3, prevents congestive reaction; 4, prevents decomposition of the solution; 5, renders solution aseptic.

Regulation of Medical Practice in Illinois.—The report of the State Board of Health of Illinois for 1889 illustrates the efficacy of its laws for the regulation of medical practice. When the law went into effect there were in the State engaged in practice 7,400 persons. Of these 3,600 were graduates from some medical college, while 3,800 were non-graduates. In other words, the graduates constituted only forty-eight per cent. of all engaged in practice. On January 1, 1890, the percentage of non-graduates to the whole number was only nine. From 3,800 the number has been reduced to 575. The total number of physicians in the State is less now than it was twelve years ago.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, June 21, 1890.

PUBLIC REGULATION OF THE MILK-SUPPLY OF CITIES.

AN idea was advanced at one of the Section meetings at the Nashville Convention that deserves careful consideration. It was to the effect that municipalities should have control of the production of the milk-supply as well as of its sale. At present the only supervision is that exercised by the Board of Health to prevent adulteration of milk. The tests required thus far have been reduced to scientific accuracy, and so far as we can judge the inspectors perform their work honestly. The results are as good as can be obtained under present circumstances. But we can exercise practically no supervision over the care of the dairies from which the milk comes. It is here that the mischief often arises. The milk, such as it is, reaches the city in as good condition as it was when it left the dairy. This is, however, to be modified somewhat when we consider how much the milk is swashed around in transit. But the trouble lies farther back. The average farmer does not exercise any great care in either feeding, stalling, or milking his cattle. As milk comes from the udder of the healthy cow it is pure, and free from germs. If it is carefully kept free from dirt, immediately bottled, or placed in small air-tight receptacles, it can be delivered to the consumer in this same state; but, as a matter of fact, no such care is taken to make the milking process a cleanly one. The milk from different animals is dumped into one large can, which is opened and reopened in the final distributing process, until the wonder is that more milk is not really spoiled than is actually the case.

Now, the new idea is to give a Board of Health authority over the source of supply. We are met at once with the objection that the city has no right to interfere with a man's private business. It has none, if the man's business does not directly concern the life and health of his fellow-citizens; but in this case it does, and concerns the most helpless class in the community—namely, infants and children, who are so largely, and at times entirely, dependent on milk for their sustenance. We do not mean that the city should go into the milk business, but we do believe that the inspector's power should go farther back than the milk-can. It should go to the dairies themselves. Milk producers should be compelled to seal their milk in small receptacles as soon as it is passed, and so deliver it to customers. Much of the bottled milk delivered now is bottled in our avenues and side streets in the early morning hours.

Our inspectors have already the power to examine the animals in a dairy if tubercular disease is supposed to exist, and they have power to order the killing of suspected animals. Let the further authority be placed in their hands. Rules should be established concerning the immediate bottling of milk, and be rigidly enforced. Failure to observe them should be visited with severe penalties.

We take great pains with our water-supply, as well to quality as to quantity. Why should we not exercise the same care with our milk? A few reputable dairies have already established the new system; but, of course, it at present leads to an increase in price, and is available only for the well-to-do classes. But it is the poor who need the most relief. At present the city handlers of milk reap all the profit. The farmers are very poorly paid and make scarcely any money at all, and it is these middlemen who should bear the expense.

The value of milk as an article of diet, for well persons as well as for the sick, is coming to be more and more recognized. Adults as well as children can be kept on it, and it could replace with advantage much of our meat and heavier food, particularly in the warm weather. Therefore any measure which leads to purification of the supply in our cities deserves careful consideration. Sterilization removes many of the dangers, but it can never improve milk. It only renders it less harmful.

THE TREATMENT OF GONORRHŒA.

THE treatment of gonorrhœa, like the treatment of syphilis, is a subject which has received an enormous amount of attention and of scientific and literary labor. Despite all this, the practical management of gonorrhœa is exactly what it was ten or twenty years ago. It is true that a few assert great results for frequent and copious irrigations with water or disinfectants, but this plan has not achieved any wide recognition or endorsement.

A long communication from Dr. Friedheim, in the *Archiv fur Dermatologie und Syphilis*, upon the subject of the treatment of gonorrhœa, has recently appeared. It will excite some interest because his work has been done in Professor Neisser's clinic, and represents the results of a study of one thousand two hundred cases. Dr. Friedheim states that he sought to find that local application which would most completely kill gonococci, lessen inflammation, and promote epithelial desquamation and elimination of the microbes.

The best results, according to an analysis given of them in the *British Medical Journal*, were obtained from a solution of nitrate of silver, of a strength varying from 1 to 4,000 to 1 to 2,000. The treatment is begun by the injection of this solution in the ordinary way, from four to six times a day, the result being that at first the discharge becomes more abundant, thicker, and more purulent; but in about four days the secretion diminishes, becomes thin, and contains a quantity of epithelium. The gonococci also diminish in a remarkable manner, and after a few days disappear altogether. When this has taken place, the number of injections of nitrate of silver is reduced to two, and afterward to one, daily; and other injections, such as boric acid or some preparation of zinc,

are used as well. But, in spite of the almost total disappearance of the discharge, the one daily injection of the nitrate of silver is to be kept up for many weeks. In cases where the nitrate of silver could not be borne even in weaker solutions than those above mentioned, salicylate of mercury, or thallin, or the chloroborate of sodium was substituted with a certain amount of success; and in the very rare cases in which no antibacterial injection could be tolerated, internal remedies were resorted to. Of these, cubebs, turpentine, oil of gaultheria, oil of sandalwood, kava-kava, ichthyol, creolin, and copaiba were tried; but among these copaiba alone, and that only in some cases, was found to have any decided effect on the gonococci. As regards the danger of complications from the use of the nitrate of silver injections, it was found that this mode of treatment was really the best preventive.

CATS, COWS, AND DIPHTHERIA.

Evidence obtained over ten years ago by Mr. W. H. Powers, and recently by Dr. E. Klein, goes to show that diphtheria in man may come directly from a disease of the cow and of the cat. Dr. Klein's investigations, in particular, indicate (*The Lancet*) that there is a natural malady occurring among cats which is associated with diphtheria in the human subject. The cats suffer from broncho-pneumonia, later their kidneys are found to be large and white, with the cortex in a state of fatty degeneration. Dr. Klein finds a bacillus in diphtheritic membrane, which, when inoculated into guinea-pigs, cats, and bovine animals, produces a local tumor in which the bacillus is found to have multiplied, followed by congestion of the internal organs, broncho-pneumonia, and, at a later stage, if the animal live, fatty degeneration of kidney. When inoculated into the cow, the tumor is found to be followed in a day or two by a papular eruption on the udder. This eruption passes rapidly through the stages of vesiculation and pustulation, the pustules changing into a crust with sores beneath. But there is a difference between the guinea-pig and cat on the one hand, and the cow on the other, in the circumstance that the bacillus in the former animals is limited to the region of inoculation, but in the cow is found in the eruption on the udder and in the milk.

There seems to be quite strong evidence that there is a natural malady in cats which, when conveyed to man, is diphtheria; also, that there is a disease occurring in cows which gives rise to this peculiar cat-diphtheria when the milk of the infected cow is drank by cats.

The Cholera in Spain.—An outbreak of Asiatic cholera is reported from Puebla de Rugat, in Spain. The disease has existed there for some time, but its true nature has been recognized, or at least acknowledged, only within a few days past. Even yet the government at Madrid refuses to admit that the disease is true Asiatic cholera. Rugat is a small town in the eastern part of Spain, near Valencia, and physicians and medicines have been sent from the latter place to relieve the sufferers in Rugat. About one hundred cases of cholera have thus far been reported, and new ones are reported daily, despite the efforts of the local authorities to stamp out the disease.

News of the Week.

Berlin Congress.—An orthopædic section has been established for the International Congress.

Roosevelt Hospital Operating Theatre.—The legal difficulty concerning the will of Mr. Syms, providing for the erection of an operating theatre upon the grounds of the Roosevelt Hospital, has been compromised so that the work upon said building will soon be resumed. A gynecological operating pavilion is also in process of erection. The money therefor has been subscribed by a friend of Roosevelt Hospital.

The Ohio State Medical Society held its annual meeting in Columbus on June 4th, 5th, and 6th. The following officers were elected: *President*, Dr. W. J. Conklin, of Dayton; *First Vice-President*, Dr. D. N. Kinsman, of Columbus; *Second Vice-President*, Dr. B. L. Milliken, of Cleveland; *Third Vice-President*, Dr. D. J. Snyder, of Scio; *Fourth Vice-President*, Dr. Orpheus Everts, of College Hill; *Secretary*, Dr. G. A. Collamore, of Toledo; *Assistant Secretary*, Dr. J. A. Spence, of New Philadelphia.

The Wisconsin State Medical Association closed its annual meeting in Milwaukee on June 6th. The election of officers resulted in the choice of the following: *President*, Dr. Ladd, of Milwaukee; *First Vice-President*, Dr. F. E. Wallbridge, of Milwaukee; *Second Vice-President*, Dr. B. F. Phillips, Menomonee, Mich.; *Secretary*, Dr. J. R. McDill, of Milwaukee; *Assistant Secretary*, Dr. H. B. Ogden, of Milwaukee; *Treasurer*, Dr. Sydney S. Hall, of Ripon. The next annual meeting will be held in Madison during the first week in May, 1891.

The Montana Medical Association.—At the annual meeting of this society, held in Helena on June 5th, the following officers were elected: *President*, Dr. J. S. Hammond, of Butte; *First Vice-President*, Dr. J. H. Owings, of Deer Lodge; *Second Vice-President*, Dr. George L. Treacy, of Helena; *Corresponding Secretary*, Dr. George H. Barbour, of Helena; *Recording Secretary*, Dr. Wm. Gunn, of Butte (re-elected); *Treasurer*, Dr. W. L. Steele, of Helena (re-elected). It was voted to hold the next annual meeting in Helena, the third Wednesday in April, 1891.

International Medical Congress.—In connection with the exhibition during the Congress at Berlin the German Imperial Board of Health is engaged in forming a special department for the illustration of medical and sanitary appliances. It is hoped that the various hygienic institutes and laboratories, as well as instrument-makers and others, will largely contribute to the exhibits. The larger German towns will also probably show plans of the sanitation works carried out within them.

An Ambulance System in Louisville.—An effort is being made by the Commissioners of Public Charities in Louisville, Ky., to establish an ambulance service in that city in connection with the municipal hospital. It is rather strange that a city of such a size should have no provision for caring for cases of emergency.

Cardinal Lavigerie is having negroes trained as medical practitioners at Malta, and several have already completed their education and proceeded to Central Africa.

The Mississippi Valley Medical Association will hold its seventeenth regular annual meeting at Louisville, October 8, 1890. The profession of the Valley is invited to attend and to bring their wives and daughters. Kentucky promises to outdo herself in hospitality on that occasion, and the ladies will be given especial attention. Titles of papers should be sent to the Secretary, Dr. E. S. McKee, 57 W. 7th Street, Cincinnati, as early as possible. Gentlemen who read papers at the last meeting will confer a favor if they will send copies or reprints of the same to the Secretary, to complete a collection of the transactions.

The Death of Dr. Francis Siredy, of Paris, is announced. Dr. Siredy was born in 1831. He was at the time of his death a member of the Académie de Médecine.

Death of Dr. John A. Bosch.—John A. Bosch, M.D., died June 6th, at twelve o'clock noon, at St. Luke's Hospital, of phthisis pulmonalis et laryngis. Dr. Bosch was a graduate of the College of Physicians and Surgeons in the city of New York, class of 1885, and an ex house surgeon of Charity Hospital, on Blackwell's Island, staff of 1886 and 1887. He went abroad soon after leaving the hospital, returning to New York late in the fall of 1887. He practised a while in this city, until compelled by ill health to leave, when he moved to Poultney, Vt. The climate there proving too severe, he, with his wife, repaired to Guayama, Porto Rico, where, instead of improving, he grew worse, and finally returned to New York for treatment. He entered St. Luke's Hospital June 3d. The doctor's death will be lamented by a host of his friends and professional associates, and his wife and other members of his family will be the recipients of condolences from all who knew him.

Tompkins County (N. Y.) Medical Society.—At the annual meeting of the Tompkins County Medical Society, held at Ithaca, N. Y., on the 29th ult., Dr. Winslow was re-elected President, which office, however, he declined. Dr. Eugene Baker was therefore elected President, Dr. J. A. Lewis, Vice-President; Dr. John L. Babcock, Secretary; and Dr. Edward Meany, Treasurer and Librarian. This society meets once a month, and with the assistance of those of its members who are members of the faculty of Cornell University, these meetings are made very interesting and valuable.

The Meharry Medical College (colored), Nashville, Tenn., has recently added a new building, with a large, well-lighted, well-ventilated lecture-room, situated across the street from the older one, and for use by both the medical and the dental departments. Professor George W. Hubbard, who has been so active in building up this college, says he wants graduates to know practically more about drugs than he was taught at his alma mater, and therefore requires them to spend some time in the pharmaceutical department connected with the same institution. This is an example which might with advantage be followed by other colleges.

The North Dakota Medical Association has been organized, and held its annual meeting in Jamestown, N. D. The election of officers resulted in the choice of the following: *President*, Dr. Coe, of Mandan; *First Vice-President*, Dr. Shurlock, of Fargo; *Second Vice-President*, Dr. Merchant, of Ellendale; *Secretary*, Dr. McIntyre, of Hillsboro; *Treasurer*, Dr. Rounsevell, of Larimore; *Censors*, Drs. Rankin, of Jamestown, and Wellspaugh, of Park River. The next meeting will be held at Fargo on May 26, 1891.

Medical Society of Virginia.—The twenty-first annual session of this society will be held at Rockbridge Alum Springs, Va., September 2, 3, and 4, 1890.

The Southern Dental Association will hold its annual meeting in Atlanta, Ga., on July 15th.

The French Association for the Advancement of Science, which has an important medical section, meets at Limoges, August 7th to 14th.

Dr. Henry T. Child, of Philadelphia, died on June 15th, aged seventy-four.

Dr. Edward Malone, of Brooklyn, died on June 16th, aged fifty-eight.

A Healing Shrine at Alleghany City.—The daily papers state that on June 13th, St. Anthony's Day, at least ten thousand afflicted people from all parts of the country gathered at Father Mollinger's church, in Alleghany City, to be healed and take part in the celebration. It was a curious assemblage of the lame, deaf, and blind, drawn together by the reports of Father Mollinger's miraculous cures. The afflicted began to arrive on the day before, and on the night previous five thousand were camped about the church, sleeping on floors, doorsteps, porches, and the ground. The services began at daybreak and continued all day and until late in the evening. Thousands were unable to gain admission to the church, and all day they stood in the hot sun, awaiting their turns to be cured.

The New Rules of the Commission in Lunacy.—Several changes have been made, in regard to the mode of committing the insane, by the present Commission in Lunacy. One is the medical certificate of lunacy, which goes into effect July 1st. After that date each examiner in lunacy must furnish a statement concerning each patient, giving the name, sex, age, nativity, color, occupation, number of previous attacks, date of the present attack, and other facts designed to give the commission a clear idea of each person so confined in the State asylums. Another rule which is now in force requires that every physician who wishes to become an examiner in lunacy must not only get his certificate as heretofore, but must file a certified copy with the Commission in Lunacy. The Commission has ordered that the officer in charge of each insane asylum be directed not to permit the service of any legal process whatever upon any insane patient, except upon the order of a Judge of a court of record, which shows that the Judge had notice of the fact that the person sought to be served was at the date of the order an inmate of such an institution.

The Pasteur Institute of this City.—A donation sufficient to erect and equip a Pasteur Institute has, it is said, been offered to Dr. Gibier, who is now conducting such an institution on a limited scale.

An Intercolonial Australasian Medical Congress will be held in Sydney, probably in September, or October, 1891. The President-elect is the Hon. Dr. MacLaurin.

A Wink and a Click.—Dr. J. O. Greene reports the case of a woman with more or less hypertrophied process going on in the ear, who by winking could produce a distinct clicking. This was a distinct objective noise, which one could hear by connecting one's ear with hers, and was distinctly produced every time she winked the right eye.

Monuments were Recently Raised in Vienna to Professors John and Theodore Oppolzer, father and son.

"Strychnine Pick-me-ups."—The *British Medical Journal* gives currency to a report that American ladies are in the habit of using strychnine lozenges as a "pick-me-up." They are said to be small doses of putty-colored gray, each containing a thirtieth of a grain of strychnine. American ladies will, no doubt, be interested in learning that they have this addition to their other picturesque habits credited to them by observant foreigners.

Andrology.—There is a gynecology, or science of woman, and now we learn that there is an "andrology"—which means, we presume, the science of man, and more particularly of man's diseases. "Andrology" has no lexicographical existence, or, at least, it is not to be found even in Foster's comprehensive work; but the word has been adopted as a part of the title of the "American Andrological and Syphilographical Association," so that now the profession may expect to have the "andrologist" as well as the gynecologist.

Fœtus in Fœto!—Dr. Kotisko, of Vienna, has presented a preparation taken from an abdominal cystic swelling in an infant five weeks of age! The cyst was a retro-peritoneal one, which contained the skull, buccal cleft, with tongue and underjaw well formed, while the extremities could be distinctly traced. This formation of "fœtus in fœto" was presumed to be the formation of two embryos on the same site, where the one in its development embraced the other, and thus retarding or suspending the growth of the enveloped.—*Medical Press.*

Rib-section Regeneration.—At the Vienna Medical Society, Professor Kundrat has shown the chest of a youth, aged sixteen, who died ultimately of varicose bleeding from the œsophagus, and who had resection of the ribs performed on account of empyema of the pleura. At the Congress this operation was much commented on for the deformity caused after the operation, owing to the bones not being restored. Here was a case with the bony parts quite restored.—*Medical Press.*

The Vienna Ophthalmic Surgeons who have had the wife of the Shah under their care have each received $4,000 for their services.

Dr. Laveran, of the Val-de-Grâce Hospital, in Paris, has received a prize from the French Institute for his researches on the hæmatozoa of malaria.

Pasteur Cranks.—If there is anything certain regarding the various Pasteur institutes for the prevention of rabies, it is that they make a great focus for irrational cranks of various descriptions. A man bitten twenty years ago by a dog "supposed to be rabid," reads of the "Pasteur Institute," gathers up his worldly goods, and comes to New York for inoculation. People who have been scratched by a cat, kicked by a cow, bitten by a horse, or pecked at by an angry hen, are in a state of mind as to whether they should be inoculated or not. Nonsense.

New Hospital in Birmingham, Ala.—The new county hospital in the suburbs of Birmingham is nearing completion. It is a red brick building, 265 × 68 feet, one story high. There are four wards, which will accommodate about one hundred patients. The ground on which the hospital is built was a gift from Dr. J. R. Smith.

Obituary.

JOSEPH W. HOWE, M.D.,

NEW YORK.

A DESPATCH from London announced, on Saturday last, that Dr. Joseph W. Howe, of New York, who was a passenger on the steamship Umbria, had died, June 7th, of a stroke of apoplexy.

Dr. Howe was born in New Brunswick, British America, September 30, 1843. He attended a grammar school until fourteen years of age, when he entered the office of the *Colonial Times*, belonging to his father, to learn the business of printing, and subsequently joined the reportorial corps of that journal, and reported, in 1861–62, the official debates in the Provincial Parliament. In 1863 he began studying medicine, and was graduated from the medical department of the University of the City of New York in 1866. Then he became junior assistant in Bellevue Hospital, and later on house surgeon. In 1868 he was appointed Clinical Professor of Surgery in Bellevue Hospital, which position he held until 1882.

He established a large practice of his own in 1867, and soon after became consulting surgeon to the Charity Hospital, and visiting surgeon to St. Francis Hospital. He was on his way to recuperate his health, and also to attend the International Medical Convention to be held in Berlin. Dr. Howe was a Royal Arch Mason. He was a member of the New York Pathological Society, the County Medical Society, the New York Academy of Medicine, and wrote several works, among them "Winter Homes for Invalids," "Breath," and "Emergencies."

Dr. Howe was for a long time in feeble health, the consequence of an infection received during an operation upon a patient. His brave resistance to this depressing malady constantly brought out those finer qualities of mind and soul which were only known and appreciated by his intimate friends. In all this he gave an example of fortitude seldom seen, even in a profession noted for its self sacrificing spirit, and his death added another martyr to duty, and another sacrifice to suffering humanity.

At a meeting of the Medical Board of St. Francis Hospital, held June 18th, Dr. J. H. Ripley offered the following, which was unanimously adopted:

Whereas, The Medical Board of St. Francis Hospital have heard with profound sorrow of the death of our colleague, Dr. James W. Howe; be it

Resolved, That we desire as individuals, and as a Medical Board, to express our appreciation of our late fellow-member. As a bold and successful surgeon, always equal to the emergency, we valued his services in our institution. As a man of moral courage, ready to defend, by word or act, whatever he believed to be right, we respected him. As a frank, unselfish, large-hearted friend, we loved him.

Resolved, That a copy of this testimonial be sent to the bereaved family, and also to the Sisters of St. Francis Hospital.

Resolved, That these resolutions be spread upon the minutes, and be published in the New York MEDICAL RECORD, and also in the New York *Medical Journal.*

CARL H. LELLMAN, M.D.,
WALTER R. GILLETTE, M.D.,
J. H. RIPLEY, M.D.,
GEORGE F. SHRADY, M.D.,
GEORGE M. EDEBOHLS, M.D.,
Medical Board.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Second Annual Meeting, held at Mott Memorial Hall, New York, June 3 and 4, 1890.

J. Lewis Smith, M.D., President.

(Continued from page 695.)

Some Manifestations of Rachitis not always Associated with Severe Bone Changes.—Dr. Walter L. Carr, of New York, from a paper on this subject drew the following conclusions: That rachitis is a disease of nutrition; it manifests itself in early life because that is the period of physiological growth, and anything which prevents or retards food assimilation will tend to cause or aggravate the disease; the chemical changes produced by malnutrition are not well understood; the symptoms of rachitis are often nothing more than catarrhs of the alimentary and respiratory tracts, delayed dentition, muscular weakness, and nervous irritability. Under proper hygienic and dietetic conditions these symptoms disappear.

A Fatal Case of Purpura Hemorrhagica.—Dr. Henry Jackson, of Boston, related the history of the case, that of a child which had been previously healthy, having had only an attack of measles from which it had made a good recovery. In June last he was sent for, and found the child playing in the yard, but peevish, and presenting small hemorrhagic spots on the legs and back, and one hemorrhagic bleb on the lip. During the day he passed a little blood with the dejections, and during the remaining days—the attack proving fatal in four days—had nosebleed, hemorrhage from the bladder and bowels, and hemorrhages into the skin. During the last three years a few cases of this kind had been reported, to which had been given the name by some authors of purpura fulminant or purpura foudroyant. It remained to be determined whether these cases had any connection with purpura, or whether they represented as yet an unknown infectious disease whose chief symptoms were seen in petechial hemorrhages similar to those seen in purpura. He thought it should probably be classed as an infecticus disease. It had been pretty well shown the hemorrhage was not due to any change in the blood itself. Some claimed there was a change in the walls of the vessels. It would be difficult to understand, however, how a disease so rapid in its onset should be due to a chronic endarteritis. The author was disposed to think there was some change in the vaso-motor nerves, probably produced by some micro-organism.

Purpura Hemorrhagica following Whooping-cough.—Dr. Earle, of Chicago, had within three weeks lost a child from purpura hemorrhagica following recovery from whooping-cough. He had treated the latter disease by a spray of carbolic acid solution, and the question suggested itself to him whether this might have had any influence in bringing on the fatal purpura hemorrhagica.

Fatal Purpura Hemorrhagica following Lancing of the Gums.—Dr. W. D. Booker, of Baltimore, related the history of a case in a child, eight months of age, which had recovered from summer diarrhœa, and was very nervous and restless. *The Lancet* had at that time rather advocated lancing the gums, under certain conditions, and this he did in the case of two incisors which were hard and white. Very little bleeding occurred at the time, but later it renewed and continued until checked, and then started from the lower gums; hemorrhagic spots formed under the skin, and, after four days, the child died. The autopsy showed some characteristic spots in the intestine. There was nothing to account for the purpura hemorrhagica.

Regarding the Pathology, Dr. A. Jacobi said no one would at present look to the condition of the blood as the cause of the hemorrhage; it must be in the blood-vessels or germ invasion. It was seen more commonly after measles than almost any other affection, and it seemed probable the micro-organism of this disease predisposed the blood-vessels to purpura hemorrhagica. Thrombic deposits in the lower extremities were not infrequent after measles.

The Disease Fatal before the First Year.—Dr. Rotch, of Boston, had seen altogether five or six cases of purpura hemorrhagica, and in no instance had he seen a baby under one year recover from it. He thought it was a germ-disease, and not simply dependent upon a condition left by some other disease. In none of his cases had it followed measles. One blooming baby died within forty-eight hours after the commencement of the purpura hemorrhagica.

Of Septic Origin.—Dr. Koplik thought in future we would have to look to some septic origin, and Dr. Fruitnight mentioned two fatal cases occurring soon after birth in infants whose mothers had puerperal fever.

The President said that in the Infant Asylum they also recognized syphilis as a cause.

Some Observations on the Stomach Capacity of Infants.—Dr. L. Emmet Holt, of New York, read a paper in which he gave the results of measurements of the capacity of the stomach after death, in one hundred and seven infants and children. A good deal of care had to be exercised not to over-distend the organ. Finally, he had adopted the rule to introduce sufficient water simply to straighten out the rugæ. In general it could be stated that, beginning with a capacity of one ounce at birth, the average child's stomach continued to gain one ounce a month up to the sixth month, and after that half an ounce a month until the end of the first year, so that it contained at that period eight or nine ounces. There were exceptions in children of unusually small size, and where the stomach was pathologically distended. But there was no such proportion between the weight of the child and capacity of the stomach. For instance, in four cases the stomach held one ounce, while the weight was three, five, seven, and nine pounds respectively; seven children weighed seven pounds, while the capacity of the stomach was one, one and a half, two, two and a half, five, and six ounces respectively, and so on.

While he did not recommend that because a child's stomach capacity at a certain age was so much, that quantity of food should always be administered, yet he did not think it should be much in excess. The stomach was extremely distensible, and might readily become dilated by administering a quantity in excess of its normal capacity. His observations showed also that physicians were likely to mistake dilatation of the transverse colon for dilatation of the stomach; that the stomach was essentially of the same shape from the first month until the third or fourth year. He had never seen the vertical stomach pictured in the books as present in infants; it lay somewhat oblique.

The Technique of Intubation.—Dr. Dillon Brown was the author. He had seen a great many cases of intubation, and he desired to present some of the practical points derived from his experience, and especially to call attention to the many badly made tubes and the many dangerous modifications of the O'Dwyer tube, which were sure to bring disparity upon one of the most brilliant and important operations of modern times. The difficulties of the operation had been greatly underrated. While it required but a few seconds to insert the O'Dwyer tube, and the immediate results were most brilliant and gratifying, yet he knew of no operation in surgery which was more brutal and shocking than the efforts of an unskilful man to intubate the larynx. He ventured the opinion that the great majority of deaths reported as due to the pushing down of membrane were really due to apnœa from unskilful and prolonged attempts, or to asphyxia from forcing the tube through a false passage. Neither Dr. O'Dwyer nor himself had ever had death on the table due to pushing down the membrane, although they had operated on nearly seven hundred cases.

All the modifications of the O'Dwyer tube which had been suggested or tried had previously been thought of and abandoned, because faulty, by Dr. O'Dwyer himself. The different sets used by Dr. O'Dwyer and himself were shown. The manner of making them, which was difficult, and therefore costly, was explained, and they were contrasted with the dangerous models in the market.

Simple but Efficient Medication in Pediatrics.—Dr. C. W. Earle, of Chicago, in a paper with this title, warned the younger members of the profession against the evil and too prevalent habit of always prescribing when first called to a patient, even before it was possible to make a diagnosis, and before it was known that any medicine was indicated; or changing the drugs when there was no real need of it, and thus having a table covered with partly emptied bottles at the end of the case; of combining numerous drugs in a single prescription; of giving nauseating preparations. Nearly all drugs now recognized as useful could be administered in a form pleasant to the taste.

The views expressed in this paper were heartily endorsed by Drs. Carr, Holt, Seibert, Koplik, and Fruitnight, who believed in testing single remedies in an agreeable form, rather than in compound prescriptions.

Discussion—The Use of Alcohol in the Treatment of the Diseases of Children.—Dr. August Seibert opened the discussion with a short paper, and was followed by Dr. Winters.

Dr. Seibert said that, sentiment laid aside, alcohol had its uses in the treatment of diseases of children. We could not entirely discard it because harm sometimes resulted, any more than we could discard opium for the same reason. Nor could we determine its full action in diseases in every direction, any more than that of any other drug, and our views should be modified regarding its uses by the extent of our knowledge. Its chief action in disease was a stimulating one, and its chief influence was upon the nervous, circulatory, and digestive systems. It was useful in counteracting the nerve-depressing influence of typhoid, intermittent, and some other affections. The organs of circulation responded very actively to it, the heart was able to do better work under its limited influence in disease, and we were therefore inclined to give it in diphtheria and some other affections. While the digestive organs were excited to increased action under alcohol, yet the action of the gastric juice was interfered with, and digestion in the stomach influenced unfavorably. It should not, then, be given where the stomach was affected, or as long as it was possible to keep up nutrition by the stomach. It was called for oftenest in acute infectious diseases; as a rule he preferred whiskey, gave it in gruel as an enema, or by bathing, and used large quantities if any.

No Fixed Rules.—Dr. Winters could give no fixed rules governing the use of alcohol in acute diseases in childhood. Each case must be a rule unto itself. In practice he found himself making a great distinction, according to whether alcohol was used for its effect upon the heart and circulation or for an indirect effect through its tonic action. In the first instance he gave it as a stimulant to tide over an emergency in acute diseases, especially pulmonary diseases. It was seldom called for in lobar pneumonia; in broncho-pneumonia he seldom used it until the inflammatory stage had pretty well passed. In all pulmonary affections in which the superficial veins became full he used it early and constantly. In all acute diseases in which there was much restlessness, and sedatives failed to soothe, alcohol would usually produce a sedative effect. If there were delirium, or indications of cerebral congestion, alcohol would likely do harm. In acute infectious diseases, excepting diphtheria, he hardly ever gave alcoholic stimulants.

Large Quantities of Alcohol in Diphtheria and Broncho-pneumonia.—Dr. L. E. Holt had been surprised to find how large quantities of alcohol children could bear who had diphtheria or broncho-pneumonia, thrive under it, and have no cerebral symptoms produced by the action of the drug. In administering it one should be guided by the effect produced rather than by the quantity.

An Antidote to Toxæmia.—Dr. J. H. Fruitnight had found alcohol apparently an antidote to the toxæmia of diphtheria, large quantities being borne without producing cerebral symptoms.

Gives Alcohol in Diphtheria and Typhoid Fever.—Dr. Vaughan, of Ann Arbor, relied almost entirely upon alcohol in typhoid fever as it was seen among children in Michigan, and seldom found any other drug called for in mild cases of diphtheria.

Alcohol not Called for in Typhoid Fever.—Dr. H. D. Chapin said that typhoid fever as it existed among children in New York was a mild affection, and seldom if ever called for alcohol.

Contra-indications to Alcohol.—Dr. A. Jacobi mentioned some contra-indications, especially the presence of cerebral symptoms, or symptoms of cerebral congestion.

Summer Diarrhœa in Infants.—Dr. C. W. Townsend, of Boston, gave on this paper a general study of summer diarrhœa in infants treated the past three years at the Sea-shore Home, a detailed study and account of each case, regarding symptoms, treatment, weight, etc., having been kept. He divided the cases into those of cholera infantum, of gastro-intestinal catarrh, and of intestinal catarrh. Altogether there were two hundred and thirty-six cases. The change of air from the heat of the city to the country was alone sufficient in some mild cases to effect a cure, and in severe ones it caused a marked improvement, but in the latter a change of diet was also called for. The majority of cases had a change of food to a mixture composed of milk, some farinaceous articles, as barley, etc. They did better the past two years, during which sterilizing the food had become the custom. Among drugs used were bismuth, salicylate of soda, lactic acid, and resorcin, but no general conclusions regarding their value were reached. Lavage of the large intestine had been practised in a few cases, and he was encouraged to continue it. He had not tried stomach washings.

Contribution to the Chemical Study of the Summer Diarrhœa of Infants.—Dr. V. C. Vaughan, of Ann Arbor, said the proof was becoming stronger and stronger that the summer diarrhœas of infants were not due to a specific micro-organism, but to the proteids of different varieties of germs. The basis of this paper was experiments with three varieties of germs sent him by Dr. Booker, of Baltimore, which had been isolated from the contents of the intestines in diarrhœal cases. In his first contribution Dr. Booker had reported eighteen varieties, and in his second had added fifteen more. Those sent to the author were numbered E, K, and S. With the chemical results of these germs upon albumin this substance acquired poisonous properties, so that when injected into the skin of dogs it produced vomiting and purging, and, if a sufficient quantity were used, death. Among his conclusions was, therefore, that any germ which was capable of growing and producing an absorbable poison in the intestine should be considered a pathogenic germ; that it was not necessary the germ itself should be capable of growing and causing disease and death when injected into the skin and blood in order to give it a place among the pathogenic varieties.

Some Points in the Etiology and Treatment of Diarrhœal Diseases of Infancy.—Dr. F. M. Crandall, of New York, read the paper. A tabulated history of one hundred and thirty-five cases was given, and several hundred cases previously seen partly formed the basis of the study. Like other observers, he found children over two years almost entirely exempt, moisture and heat gave no indications of the number of cases occurring during the several summer months. Injections had done good; he used two to four quarts, with salt or borax, thus washing the bowel out thoroughly, but indiscriminate irrigation in ordinary diarrhœa was to be condemned. Among the

indications were small mucous passages, straining and tenesmus, pus, clear mucus, or blood in the stool. Acids were more commonly useful than alkalies. The latter seemed most efficacious in the early stage, marked with sour vomiting.

Dr. Chapin read results of experiments regarding the effects of sterilization on the solubility of the caseine in cow's milk. It seemed to coagulate in smaller clots after sterilization.

Starvation as a Means of Sterilizing the Intestine.—Dr. Booker gave at some length his studies of the bacteria of the intestine in diarrhœas, and said that, so far as sterilization by way of the stomach was concerned in the treatment of diarrhœas of infancy, he thought it offered little hope of success. Milk reached the intestine before the juices of the stomach could manifest sterilizing or disinfecting effects. We were to look rather to starvation, and change of food according to the condition of the stools. In the acute cases he had obtained benefit from intestinal irrigation.

Dr. Fruitnight depended mostly upon change of air and regulation of diet.

Dr. Holt did not think we could disinfect the intestine, especially the lower, by drugs taken into the stomach. He divided the diarrhœal cases into two classes, the first including those in which there was no more than a superficial desquamation of epithelium, the second in which there were actual inflammatory changes.

Dr. Blockader said one of the best ways to prevent absorption of the bacteria or their products was to sustain the vital powers of the child.

A Case of Congenital Influenza.—Dr. C. W. Townsend read the history of the case. The mother had influenza, and the infant had symptoms like the mother which he could account for in no other way than on the supposition it was influenza. It recovered.

In the discussion which followed the President said he had seen one case of influenza in a child of four months, Dr. Fruitnight one in a child of six weeks, while Dr. Northrup doubted whether the disease ever occurred in those under two years, and others testified to its rarity in young children.

Case of Cardiac Anomaly.—Dr. John Dorning, of New York, presented the heart of a child which died, aged ten years, and which during life had attacks relating to obstructed circulation, such as dyspnœa, cyanosis, etc. There was a heart murmur. The autopsy showed the right ventricle very much hypertrophied, the heart as a whole much hypertrophied, weighing fourteen ounces; the left auricle and left ventricle not much hypertrophied. The aorta arose from the right ventricle, the pulmonary artery from the left ventricle, the foramen ovale patent and having acted undoubtedly as the safety-valve. The child had lived through an attack of pertussis.

Effects of Asphyxia in the Newly-Born.—Dr. A. Jacobi presented a child, four years of age, as illustrative of a class of cases of semi-paralysis and arrested mental development, epilepsy or idiocy, caused by asphyxia of longer or shorter duration immediately after birth. He said he had seen scores of such cases.

Etiology of Empyema in Children.—Dr. Henry Koplik, of New York, read a preliminary paper on his bacteriological study of empyema in children seen in private practice and in the wards of Dr. Scharlau at the Mount Sinai Hospital. There were twelve in all. There were seven belonging to the characteristic group in which the pneumococcus of Fraenkel and Weitzelbaum was shown in pure form, tested by inoculations on animals. In three no characteristic micro-organism was found; in one the tubercle bacillus was found in the pus, while in another, a baby of eight months, there was a pyæmic cause arising from an abscess of the foot, the streptococcus pyogenes being found. Thus it would be seen what a large proportion (seven of the twelve cases, and perhaps some or all of the three giving doubtful results in the experiments) of complicated processes there were in the lungs of an acute character, and which might be effectually combated by early and proper treatment. In two of the seven only serum was found at the first aspiration, but it contained streptococci, and soon became purulent.

A Case of Empyema, with Expectoration of Pus — Thoracentesis—Recovery.—Dr. J. H. Fruitnight read the history of the case, which occurred in a girl, eight years of age, who had recovered from typhoid fever, had pleurisy in November, presumably purulent, but thoracentesis was declined until after pus was expectorated. Under washings of the pleural cavity and hygienic conditions the child recovered, and now showed little or no collapse on that side.

How to Prevent Diphtheria.—Dr. A. Caillé in this paper discussed municipal control in New York. His remarks were based on the modern view that diphtheria was due to a micro-organism which usually became implanted on the upper air-passages, and that moisture and want of sunlight were favorable for its propagation. Measures against the disease related, first, to the abolition or destroying of the poison; second, to the prevention of infection when it existed. Separate headings related to the schools, both public and private, the homes of the people, hospitals, disinfecting stations, isolating hospitals, and street cleaning. Schools, he said, were the chief sources in spreading the poison, and there should be physicians to examine the children's throats every morning, and all with catarrhal or other changes should be sent home and to the family physician. The services of three hundred physicians for about an hour daily would be required, say on a salary of three hundred dollars a year, costing the city about one hundred thousand a year. As to tenements, he thought there should be an annex for all waste-pipes. Other measures already in use by the Health Department were explained.

How to Prevent Scarlet Fever.—The President of the Society read a paper on this part of the general discussion on "How to Prevent Diphtheria and Scarlet Fever." The micro organism of scarlet fever had not been positively ascertained, but its effects were known from clinical observation. The contagiousness probably did not cease until after desquamation had passed, and it had been said the discharges from the otitis due to it were contagious. Quarantine in a small room attached to one of the wards at the Foundling Asylum in this city had been sufficient for scarlet fever, but not for measles. The contagious element was more fixed and less diffusible in the former. It remained in clothes a long time. Most prophylactic measures consisted in isolation of the patient, disinfection of the person and air which surrounded him, and of objects and persons in close relation with him. He called particular attention to the danger in books handled by the sick with scarlet fever, for in them the contagious element remained a long time. At his first visit he wrote a prescription for carbolic acid and oil of eucalyptus, of each one ounce; spirit of turpentine, six to eight ounces; mix, add two tablespoonfuls to a quart of water, put in a broad basin and maintain a state of constant simmering over an oil-stove. He also ordered an inunction of the entire surface of the patient every three hours with carbolic acid and oil of eucalyptus, each one drachm; sweet oil, seven ounces. A solution of corrosive sublimate might with advantage be applied on a probe and cotton to the tonsils and pharynx, and ten drops of a solution of two grains to the pint syringed into the nostril every two hours in the young infant. Then there should be constant ventilation during the active period of the fever, no article should be sent from the room unless properly disinfected, new families not allowed to move into the apartments before proper disinfection, the physician should disinfect his hair and entire person, and not wear the same outer clothing when going to see midwife cases.

Officers were elected as follows: *President*, Dr. T. M. Rotch, of Boston; *First Vice-President*, Dr. V. C. Vaughan, of Ann Arbor; *Second Vice-President*, Dr.

Joseph O'Dwyer, of New York; *Treasurer*, Dr C. W. Earle, of Chicago; *Secretary*, Dr. W. D. Booker, of Baltimore; *Recorder*, Dr. W. P. Watson, of Jersey City; *Member of Council*, Dr. W. P. Northrup, of New York.

MEDICAL SOCIETY OF THE STATE OF NEW JERSEY.

One Hundred and Twenty-fourth Annual Meeting, held at Schooley's Mountain, June 10 and 11, 1890.

B. A. Watson, M.D., President, in the Chair.

Permanent Delegates. — A resolution was offered, to be acted upon next year, providing for the election of permanent delegates by county societies.

The President's Address.—Dr. B. A. Watson chose as the subject for his address, "A Historical Sketch of Surgery—Ancient, Mediæval, and Modern," going over the ground as thoroughly as was possible in the course of the two hours consumed in reading the paper. He mentioned not only the important discoveries and special fields of advancement in surgery during the present century, but also ventured to name some of those worthy of special mention during this as well as former periods.

Let us dedicate a monument, he said, to those who have immortalized their names on earth by untiring efforts in behalf of suffering humanity.

Hydrophobia.—Dr. Paul Gibier, of New York, present by invitation, read the paper. The period of incubation had been stated to have varied in man from a few days to two years. It was greater in man than in animals, because the former was less susceptible. He believed death was more frequent in animals because the latter received no treatment. He knew of no case in which the disease had been cured in man after it had once manifested characteristic symptoms. But instances were not rare in which dogs had returned to a normal state after showing unquestionable rabies. Hens and birds recovered spontaneously. Birds once affected subsequently had immunity. Symptoms appeared sooner when the virus was introduced into a vein than when it passed, as seemed to be the case, by way of the nerve-tissue to the central nervous system.

Passing to the results of the inoculative process of Pasteur, he quoted statistics from different institutes founded since 1886. The percentage of deaths among persons bitten by mad dogs, untreated by inoculation, had been about eight per cent.; with inoculations, during 1886–87, it had been about 1.1 per cent.; during 1888 it had fallen to about 0.67 per cent., covering hundreds of cases. It was thought possible to reduce it to nearly zero.

Inoculations after the development of hydrophobic symptoms were useless, yet he had received one patient, a doctor from Illinois, at the institute in New York, who had already complained of tingling sensations at the seat of the bite of six weeks before. These sensations disappeared after the inoculations, and the patient, also his daughter, who had been bitten by the same dog and received treatment, had since remained well. He had treated in all about thirty patients at the New York institute since it had been opened in February last, with no deaths.

Quinine in Epidemic Influenza.—It appeared from the report of the Standing Committee that during epidemic influenza throughout the State, physicians found quinine at an early stage, or even later stage, in too large doses, produced a tendency to congestion and pneumonia. Many had found antipyretic drugs increase the tendency to heart failure.

To Investigate New Jersey Dairy Cows.—Dr. Coit called attention to the fact that the feeding and health of dairy cattle in the State, had not been made a subject of investigation by the medical profession, as it should, and offered a resolution, which was adopted, authorizing the President to appoint a physician from the several county societies to inquire into the feeding and condition of dairy cattle in their respective counties.

Does the Early Administration of the Salicylates in Acute Articular Rheumatism Prevent Heart Complications?—Dr. E. J. Marsh opened the discussion with a review of this mode of treatment as it had been practised by some of the most reliable authorities since its introduction, about fifteen years ago. When he was a student the prevailing treatment was the alkaline, as practised by Dr. Fuller. This was thought not only to relieve the pain and swelling, but also to ward off heart complications, and Dr. Fuller had stated that, out of four hundred and seventeen cases which he had treated by alkalies, only four developed cardiac trouble. Yet hundreds of cases of cardiac complication continued to develop, and the profession was ready to try the salicylate treatment as soon as reports of its success in Germany reached this country. In 1876 Dr. Alonzo Clark tried it in Bellevue Hospital, and reported several cases in which salicylic acid had a very marked effect in diminishing fever, pain, and swelling of the joints, and in causing early convalescence. This experience was soon repeated at the hands of many practitioners, and at first cardiac complications were likewise thought to be less frequent, but time had not substantiated the latter view. Professor Flint had recommended, indeed, continuance of the alkalies to prevent heart complications, while the salicylates caused earlier relief from the joint affection. It then began to be questioned whether there were not more or earlier relapses after salicylate treatment than without. In discussions at the London medical societies the fact was brought out that the treatment of acute articular rheumatism, almost universally resorted to in the hospitals in that city, included salicylates. But it was not made to appear that heart complications were less frequent, while it had been pretty well agreed that when a heart murmur had formed the salicylates had no influence in checking the cardiac inflammation. Dr. Loomis, in his recent book, had stated that the treatment by salicylates increased the liability to heart complications, but this was the strongest adverse opinion which he had seen.

In the discussion which followed, Dr. Halsey expressed the view that salicylates not only did not control heart complications, but aggravated them; while Dr. Baldwin, who was himself a sufferer from rheumatism, continued the use of the salicylates longer than usual, and found they acted, as it were, as a prophylactic, recurrences being less likely when so used. Combined with oleic acid, it relieved pain in rheumatic nodules when applied locally, salicylate of sodium being given internally at the same time. Dr. English had found that when the salicylates drove the acute into the subacute stage, a cure would be effected earlier by giving iodide of potassium than by continuing the salicylates alone. Dr. Barker found salicylates alone did not prevent heart complications, but when combined with opium, which reduced nervous irritability, they did have this effect. When the urine was acid in one of rheumatic tendency, it seemed alkalies changed the character of the fluids so as to make them inimical to the germ, or whatever might be the cause of rheumatism.

Is Diphtheria Primarily a Local or a General Disease?—Dr. Selover opened the discussion with a paper in which he took emphatic ground in favor of the view that diphtheria is primarily a local, not a general, disease, although he admitted, with Dr. Barker, that the local manifestations might be little apparent, or be so soon followed by constitutional disturbance as to make it seem the disease was in the first place general. Fewer, who took part in the discussion, however, agreed with him that croup was noncontagious, and Dr. William Perry Watson said that in Hudson County the health authorities placed croup in the list of contagious diseases which required to be reported.

A Plethoric Treasury.—There being a surplus in the treasury, a resolution was adopted to invest thirteen hun-

dred dollars in United States bonds, making in all so invested about four thousand dollars.

To Establish a Library.—The Committee on the President's Address, read last year, did not think it advisable to divide the meeting into sections, nor to establish a journal for the transactions, but recommended establishing a local library at Trenton, which recommendation was adopted.

Delegates from other Societies.—Dr. Fleischner, of the Connecticut State Medical Society, and Drs. Cox and S. A. Fox, from the New York State Medical Society, were introduced, and the two former made some remarks favoring higher medical education. Dr. Reynolds, delegate from the New Jersey State Pharmaceutical Association, read a paper in which he showed the evils resulting from the prescribing of proprietary medicines, and named some in which the compound was not what was represented. One of the worst evils was that families bought these drugs without a physician's prescription, and thus often contracted the morphine, chloral, or other drug habit.

Fathers and Sons.—Dr. George T. Welch chose this title for a paper in which he showed some absurdities of medicine, as practised by our fathers and grandfathers, absurdities which persisted in no small degree to-day, though not always in the same form. The greatest abuse had consisted in the prescribing of nauseating mixtures. While the more intelligent were coming to recognize the fact that health was to be obtained by inhaling the cool and pure air at the sea, on the mountain, by rowing, climbing, etc., rather than by dosing with drugs, yet let him who believed that drugs were going out of date consult the prescription-books of the apothecaries, or the list of drugs imported into this country the past year. There had been over a million dollars' worth imported, the vast majority of which were for the invalid world. Of cinchona bark there had been over two million pounds, and of sulphate of quinine over two million ounces; of opium over two hundred thousand pounds; morphine over twenty thousand pounds; of balsam of copaiba over one hundred and sixty-three thousand pounds; and other drugs in like large quantities. While drugs had their place, yet it could be safely said that the sanitarian had saved more persons than all the doctors of the last century, Jenner excepted.

The Census Inquisitorial.—On motion of Dr. Lehrbach a resolution was adopted, previously adopted by the Essex District Society, to the effect that it did not consider it necessary or proper to comply with the request sent to the physicians of the United States by the Census Bureau.

Officers were elected as follows: *President*, Dr. James S. Greene; *First Vice-President*, Dr. E. T. Marsh; *Second Vice-President*, Dr. George T. Welch; *Third Vice-President*, Dr. J. G. Ryerson; *Corresponding Secretary*, Dr. William Elmer, Jr.; *Recording Secretary*, Dr. William Pierson; *Treasurer*, Dr. W. W. L. Phillips; *Standing Committee*, Drs. T. T. Smith, D. C. English, E. P. Townsend; *Business Committee*, Drs. H. R. Baldwin, W. V. Selover, H. G. Taylor, G. Van Wagenen, W. B. Johnson; *Committee on Prize Essay*, Dr. D. McLane, Forman; *Committee on Membership*, Drs. H. G. Taylor, A. W. Rogers, Charles J. Kipp.

Artificial Hypodermic Respiration.—Dr. F. Cobos, writing in the *Revue d'Hygiène Thérapeutique*, advises the use of large hypodermic injections of oxygen in cases of suspended respiration from any cause, especially in those cases in which there is some mechanical obstruction to the entrance of air into the lungs. By means of a hypodermic needle attached to a reservoir containing the gas, he produces an artificial emphysema over a considerable area. He has satisfied himself by experiments that the gas so injected is readily taken up into the blood, and there works the same changes as it does when acting upon the blood circulating in the pulmonary capillaries.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting. April 28, 1890.

Alexander S. Hunter, M.D., President, in the Chair.

The Treatment of Diarrhœa in Early Life, Dietetic, Mechanical, and Medicinal, was the title of a paper read by Dr. H. D. Chapin (see p. 697).

In Mild Cases Change of Diet Sufficient.—Dr. Joseph E. Winters said the majority of cases of mild infantile diarrhœa followed indigestion or dyspepsia, and little more was required in the way of treatment than a modification of the diet. It usually required to be diminished in quantity if not changed in character, be administered less frequently and less rapidly—for most of the patients were artificially fed—and change the diluent. Instead of diluting the milk with water, use barley-water, and it might be necessary to give lime-water.

Regarding dangerous cases, they were nearly all due, not to too frequent feeding, or over-feeding, or the use of too concentrated food, but to the ingestion of food which had undergone some change. This form of diarrhœa might occur during either winter or summer. During the recent thunder-storm a very considerable number of severe cases developed, doubtless owing to changes which had taken place in the milk. This change having taken place before the milk arrived in the city, sterilization here had no effect upon it. During the hottest days no milk was safe as food for infants unless it had been sterilized just after milking. In these acute cases milk in no form could be digested, and it was difficult to find a substitute which would nourish the child for even forty-eight hours. The substitute should be nourishing and stimulating to the nervous system. There were two articles which he used a great deal, one an animal broth, the other a farinaceous article, say barley-gruel, used together or separately. Both might be made strong enough to form a jelly when cool. To them he added a little brandy. These foods he thought were most useful in lieu of milk, but they could be employed only for a short period. First, however, all food should be stopped until the stomach and intestine had been cleared. As to modern methods in these cases, he would be afraid of the result Dr. Chapin had mentioned if the stomach-pump were used. He would not dare resort to washing the stomach in private practice. But he washed out the lower bowel, ridding it of offending material, as had always been his custom. It was likely, after clearing the intestine by some drug, washing the lower bowel, and withdrawing milk, that the stomach would stand teaspoonful doses of the broth and gruel, but if the intestinal irritation kept up he would give some sedative, and the best was opium, the first dose being small, and sufficient time elapsing for the influence of the first to have passed off before administering a second. Opium should never be administered in frequent and small doses in these cases.

Dysenteric Form.—A third form of diarrhœa in children was a form of dysentery, and might be due to cold or exposure. Sudden pain and diarrhœa came on, and after the first two or three passages blood was seen, also mucus, and finally pus. These cases were troublesome, and must be managed almost entirely by attention to diet, such food being given as could be digested in the stomach, leaving little residue. They were the cases which did best on peptonized and pancreatized foods. But diarrhœas which originated in the upper part of the intestinal tract did not, it seemed to him, do well on peptonized foods.

Treatment Depends on the Form of Diarrhœa.—Dr. Walter L. Carr referred to the empiricism of the past in the treatment of diarrhœas of children, and said we had come to recognize the fact that the treatment must depend upon the form of the disease. Simple dyspeptic diarrhœa could sometimes be relieved by very simple

measures, while inflammatory conditions had to be treated in a special manner and the drugs employed be given for a longer period. The experimenters with the newer drugs had obtained very good results, probably because they had tried them in simple dyspeptic cases which ought without them to have got well within a few days. In gastro-intestinal catarrh, calomel was one of our best drugs for increasing the flow of bile and pancreatic juice, and in that way of increasing the peristaltic action of the intestine, and removing irritating material. It might in itself have some action in preventing decomposition and the development of bacteria. He stated objections to bichloride of mercury, discussed the virtues of the salicylates and of naphthol. Said salicylate of bismuth promised to be of great efficacy, and that the indications for opium had been well pointed out by the previous speakers.

Summer Diarrhœa.—Dr. J. Lewis Smith discussed the treatment of summer diarrhœa in infants, and first spoke of the intestinal lesions, which he had examined at a great many autopsies. In all instances, or with few exceptions, there was an entero-colitis, the inflammation being most marked in the ileum and colon, especially adjoining the ileocæcal valve. There was seldom more than an arborescent appearance in the stomach and duodenum. Under four months of age there was considerable vascularity of the entire intestinal tract and also of the buccal cavity. In the severe cases, in which death took place early, this vascularity was not observed, but there was a soft, sodden appearance of the mucous membrane of the intestines. In these very cases, however, when they continued ten days or two weeks, the usual inflammatory changes mentioned were present. There was little evidence that the liver was at fault, for which formerly calomel was so much administered.

Regarding milk, we should insist on obtaining milk bottled in the country, instead of that delivered in cans. In sterilizing, he had the milk steamed two hours. If the family had no other way, the bottle could be placed on a cup in a tea-kettle, the water not touching the bottle. After long sterilization, the casein did not form such large curds in the stomach. For farinaceous food, during the last two years he had recommended barley-flour subjected to heat by boiling water for seven days. Thus considerable of the starch was converted into dextrin, which was readily digested. If the barley could not be subjected to heat for seven days, let it be a good part of one day. Even children under three months could take such food. He did not think irrigation of the stomach necessary. Bismuth was the safest and best antiseptic. Alkalies destroyed to a great extent the digestive powers of pepsine when administered at meals. Much harm had been done by opiates in advanced cases, or the so-called spurious hydrocephalic form, yet opium had a good effect in some forms in arresting peristaltic action sufficiently long to allow food to become absorbed. He had seen injury from laudanum, but not from paregoric, and in the latter the camphor had a beneficial influence.

Dr. Dorning thought it was a hopeful sign to see the profession giving attention so much to dietetic treatment of summer diarrhœa. In the first place, we should seek to induce rest in the inflamed mucous membrane, and for this reason food should be abstained from, during twelve to forty-eight hours, in the meantime, giving only sterilized water. Most children would stand egg-water. He approved of mutton broth, but objected to farinaceous foods in infants under four months. He had tried mechanical treatment twice in private practice, and had been dismissed as family physician. He began with a laxative, calomel or castor oil, and found bismuth the best antiseptic.

Washing the Stomach Caused Family Commotion, at least in Dr. Crandall's experience. The same object, cleansing of the stomach, could be accomplished by giving the child warm water, which it would soon eject.

Diarrhœa as it Occurs in the Country.—Dr. Goodridge, of Flushing, thought that diarrhœa in young children was somewhat different in country from that in city practice and led to somewhat different treatment. In the country it was usually acute when the physician was called, and was much more largely due, perhaps, to overfeeding or injudicious feeding. In such cases, the child being well nourished, it was his practice to withdraw all food twelve or twenty four hours, and this, with clearing out the bowel, usually sufficed.

Dr. Chapin said milk bottled in the country was best, but he had been told it was usually not bottled until it reached the city. In experiments on a dog he could see little difference between raw milk and sterilized milk on taking it from the stomach some minutes after its introduction through a gastric fistula.

INDIANA STATE MEDICAL SOCIETY.

Forty-first Annual Session, held at Indianapolis, Ind., May 14 and 15, 1890.

Dr. J. D. Gatch, of Lawrenceburg, President.

Dr. E. S. Elder, of Indianapolis, Secretary.

The secretary reported 844 members, and the treasurer, Dr. F. C. Fergueson, of Indianapolis, reported $1,406.81 in the treasury. An hour was spent in eulogistic speeches in memory of Dr. Thomas B. Harvey, who died during the past year. A committee, consisting of one member from each county, was appointed to attend to the enforcement of the law suppressing quackery. Dr. William Cluthe, of Tell City, was appointed chairman.

A dinner was given by the faculty of the Indiana Medical College to the members of the Indiana State Medical Society. Dr. L. D. Watterman, of Indianapolis, gracefully presided as toast master. Dr. E. S. Elder responded to the toast, "Our Guests," and Dr. E. S. McKee, of Cincinnati, to that of "Medical Journalism;" Dr. Edwin Walker, of Evansville, "The Indiana Medical Society," Dr. J. C. Sexton, of Rushville, discussed the "Relation of the Physician to Medical Education."

Officers elected: *President*—Dr. G. C. Smyth, of Greencastle; *Vice-President*—Dr. H. C. Wood, of Angola; *Secretary*—E. S. Elder, of Indianapolis; *Assistant Secretary*—Dr. H. C. Reade, of Tipton; *Treasurer*—Dr. F. C. Fergueson, of Indianapolis.

Homœopaths, Eclectics, and Regulars.—A peculiar feature was that the Homœopaths, Eclectics, and Regulars were all meeting in their annual State Convention on the same days and in the same city.

Papers were read on "Sciatica," by Dr. W. H. Thomas, of Indianapolis; "Headache in Relation to Eye Strain," by Dr. J. P. Worrell, of Terre Haute; "Acute Inversion of the Uterus," by Dr. G. T. McCoy, of Columbus; "Tonsillitis," by Dr. L. C. Cline, of Indianapolis; "Corneal Ulcer," by Dr. J. L. Thompson, of Indianapolis; "A Case of Splenectomy," by Dr. L. J. Willien of Terre Haute.

An Ischiophagus, was the striking title of a paper read by Dr. T. O. Armfield, of Tipton. It referred to the famous Tipton County twins, and gave a minute clinical history of this two-headed baby. The brains of both children were quite well developed, and the children quite handsome and exceedingly bright for their age. One would cry while the other laughed or slept, and one would experience pain while the other felt well. They were placed in a museum circuit when three months of age, and one died at Buffalo, N. Y., when eight months of age, from measles. The other died forty-five minutes later from shock, from the cold blood rushing into its veins from the dead child, and its inability to oxygenate the blood from the dead child.

What of the Day?—The President, Dr. J. D. Gatch, took for his subject, "What of the Day?" The doctor thought the destiny of the medical profession a glorious one. The great aim of science is the discovery of truth, and the proverbial veneration entertained for it by the

human mind is a sure indication that truth will be conducive to the real progress of nations and individuals. Every lover of truth is a lover of knowledge. The mind is the grand regulator of the heart. The laws of nature are all simple, and are readily comprehended by a mind of ordinary capacity when separately announced. How could it be expected that in the general enthusiasm for useful knowledge, medicine should escape, or that its secrets should escape from a scrutiny that has spared nothing? The present century of professional life indicates wonderful advance, and is keeping step with steam, with electricity, with scientific education, and with progress in every department of public interest. When one recalls the wonderful activity in the collateral sciences which are the handmaids of progression, the application of the development of physical sciences to the solution of vital problems, the remarkable development in both normal and pathological histology and histo-chemistry, the great improvements in the construction of instruments, and the introduction of new methods of investigation, it leads him to think the present century one of very great progress.

Some Emergencies Demanding Abdominal Section, a paper by DR. J. C. SEXTON, of Rushville, excited a spirited discussion. This paper was a critical review of cases coming under the author's personal observation, which had in his opinion been improperly treated, and which operation might have saved. He urged the performance of section at once in traumatic perforation. He held that administering opium in these cases is the greatest possible error. He severely criticised the policy of waiting for the subsidence of shock before beginning operation, quoting Dennis, of New York, and Price, of Philadelphia, as supporting his view. The author stated that in one of his cases the patient was "shocked to unconsciousness—pulse imperceptible, scarcely bleeding from a lacerated omentum that protruded from the abdomen"—who rallied so promptly upon filling the cavity full of hot water, that in ten minutes the anæsthetic was given and operation begun.

The essayist made reference to Dr. McMurtry's famous case of section for perforation of colon and suppurative peritonitis, and said Dr. McMurtry had added another gem to Kentucky's bright crown of surgical glories. The paper added "this honor might have come to Indiana and Rush County, for the opportunity was present, and the situation not grasped."

The diagnosis of appendicitis indicated immediate section in the opinion of the essayist. Senn and Treves do not hold this view, but advise waiting until the interval between attacks. He cited four cases coming under his observation in one year, and said that authority for the old treatment by opium and blister could not be found in any text-book or journal published in the last five years.

A case of supposed uterine pregnancy was mentioned, and the fact deplored that the abdomen was not opened, as it was clear that the woman bled to death internally.

A case of dystocia from the cicatrix left after a high amputation of the cervix was described, and the doctor held that abdominal amputation of the uterus would have been a better procedure than a high forceps delivery after cutting through the cicatrix. He condemned the conduct of some who would do nothing themselves, nor allow anything to be done, where operation alone could save life. He said we are all willing to subscribe to the doctrine of certain men, that there should be "fewer laparotomies by the many, and more by the few;" but this dictum does not excuse ignorance of the subject, nor prevent preparation for emergencies demanding prompt action.

Some of the Problems of Bacteriology, was the subject of a paper read by DR. THEODORE POTTER. He said there is no subject which has occupied so large a part of the interest and attention of the profession during the last decade as the germ-theory of disease. The medical historian of the future will describe our age as chiefly characterized by the development in this direction.

Bacteriology has entered all the fields of medicine, modifying our ideas of etiology, pathology, diagnosis, treatment, and prevention. In the broader sphere of preventive medicine it has brightened our hopes for the coming of a better day. It has stepped in with an offer of aid in the solution of some of the important questions of medicine, but problems have arisen in this work, among them being:

Questions of the susceptibility of animals to the infectious diseases; the durability of disease germs and the methods of their dissemination; of disinfection; whether each of the infectious diseases is due to a single and specific cause; of hereditary transmission.

The essayist showed how the uncertainties connected with inoculation experiments upon animals threw an obstacle in the way of reaching positive conclusions as to the specific pathogenic character of certain bacteria, as illustrated in the investigations of such diseases as cholera, typhoid, diphtheria, syphilis, etc. Either we shall have to make more experiments upon men, criminals perhaps, or we must learn more than we now know of the exact relation of animals to the infectious diseases.

Durability of Infectious Material.—As to the durability of infectious material and its dissemination, the idea chiefly emphasized was, that by means of bacteriology our knowledge had become more positive and definite. Having identified a certain material thing as the essential infecting agent, having learned the conditions of its existence and how to recognize it, we are better prepared to detect it in its hiding-places, to trace it from place to place and person to person, and to determine how long it remains dangerous.

Similarly, more definite knowledge has been obtained of the efficiency of disinfecting agents, and of the distinction between disinfectants and deodorants. Knowing what is to be destroyed, we may more easily decide whether or not our efforts to disinfect rags, sputa, fæces, hands, and instruments have been successful.

Each of the infectious diseases is probably due to a specific cause. But the investigation of pneumonia and diphtheria, for instance, has made it an open question which bacteriology does not answer with positiveness as yet. The relation between puerperal fever and erysipelas, revealed both by clinical observation and experiment with cultures, seems to show that a germ may, under different conditions, produce apparently different disorders.

Heredity.—As to heredity, laying aside for the time being secondary and predisposing causes, the question is, whether the germs or spores exist in the body at birth. The methods of investigating this problem were explained, especially as they bear upon tuberculosis. The opinion was expressed that the older ideas of the direct heredity of tuberculosis were at least exaggerated; but we are not yet warranted in asserting that neither is the disease, nor a predisposition to it, ever inherited. The laws of heredity are not violated by the prevailing opinion in the profession as regards the latter, particularly, and some able but not infallible authorities may have to recant before many years have passed. In conclusion, the writer urged that bacteriology is not merely a laboratory occupation, or a microscopic study, but a study of pathology and the causation of disease, and the problems which gather about these two great fields. It is only as we thus think of it that we shall be able to understand what it is, and what it means to the progress of medicine.

The Electric Lamp for Neuralgia.—A correspondent writes that he has several times obtained much relief, when suffering from facial neuralgia, by applying to his face an incandescent electric light. He suggests that the lamp could also be used in poulticing, laying it over a flaxseed or other form of poultice, thus securing constant heat.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DISCUSSION AT THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY ON THE REFLEXES IN CASES OF INJURY TO THE SPINAL CORD—SOME NOVEL VIEWS—THE CONDITION OF THE DEEP REFLEXES AN AID TO PROGNOSIS AND TREATMENT IN CASES OF SPINAL INJURY.

London, May 17, 1890.

At the last meeting of the Medical and Chirurgical Society the subject of discussion was, "The Condition of the Reflexes in Cases of Injury to the Spinal Cord," and was introduced by a paper by Mr. Anthony Bowlby. Mr. Bowlby stated that the conditions of the reflexes in cases of complete crushing of the cord, as observed by himself, were at variance with the recognized teaching of physiologists. He gave details of eleven such cases of spinal injury. In all of these the limbs were quite flaccid, the tendon reflexes were abolished, and ankle clonus and rigidity were absent. In most of the cases the skin reflexes were also lost, but this was not the case in all, and in some patients in whom the skin reflexes were lost they returned at a later period. In cases of injury to the spinal cord without complete solution of continuity, on the other hand, he had found the reflexes increased. Mr. Bowlby urged that as in all cases of complete crushing of the cord the deep reflexes were lost, and as spinal cords so injured were incapable of repair, operative interference was only likely to be of use when the deep reflexes were not abolished, and when, therefore, it was believed that the cord was not completely severed. The author then alluded to ten other fatal cases of injury to the spinal cord, and pointed out that in none of the twenty-one fatal cases was there found on post-mortem examination any compression by displaced bone or other condition remediable by surgical interference. The conditions found justified the belief that the cord was crushed by a forward displacement of the upper of the two vertebræ involved in the injury, and that the displaced bone was usually spontaneously restored to its normal position, or else was so far replaced as to prevent any continued direct compression of the spinal cord. He concluded that it was not yet certain whether the deep reflexes were ever lost in cases of severe injury to the spinal cord short of complete crushing, and suggested that further evidence was required to make this clear.

Dr. Howard Tooth showed sections from the spinal cords of some of the cases. In one case of complete crush he was unable to demonstrate the existence of healthy fibres in the section, which was stained with carmine, and yet there was a slight return of the reflexes on one side. He agreed with Mr. Bowlby that in cases of complete crush with loss of reflexes operation could be of no use; but if any reflexes were present there might still be a little hope.

Dr. Charlton Bastian said it had been objected to Mr. Bowlby's arguments that the abolition of reflexes in his cases might have been due to shock, or to the presence of an unsuspected lumbar lesion. The latter objection, however, could not apply in the case of surgical injuries to previously healthy cords. In some of the cases, also, the first objection was invalid, for the patients lived for two weeks, or more, after the injury, and the abolition of reflexes persisted all that time. Dr. Bastian considered that these cases of abolished reflexes had little or no chance of recovery, and no good was likely to result from operation.

Mr. Warrington Howard asked whether operation was justifiable and likely to be of benefit in cases where the reflexes were present or increased. In no one of the cases related was displacement of bone found after death, and he inquired if any cases were known of in museums where fracture dislocation with partial paralysis existed, and in which there was a condition of bone displacement remediable by operation. The removal of bone pressing on the cord might relieve irritation.

Mr. Bruce Clarke referred to a case in which the spinal cord was pressed on by displaced bone and paralysis was present; after extension under chloroform and fixation, the paralysis almost entirely disappeared, and the man left the hospital some weeks afterward greatly relieved.

Dr. Angel Money thought the matter should be carefully considered before arriving at definite conclusions. If the spinal cord was quietly divided above the lumbar enlargement were the deep reflexes lost? The cases referred to had all been instances of violence or of disease, and we could not argue from them what would be the results of neat, complete, and quiet division. He thought the absence of reflexes might be explained by the assumption of the presence of a degree of chronic shock, which, so to speak, left the cord devitalized, the molecules being deranged beyond reparation.

Dr. Cagney could not harmonize Mr. Bowlby's conclusions with accepted facts. He asked when the superficial reflexes returned in cases in which all reflexes had been lost, and how far the prognosis would be modified by this.

Mr. Langley Brown said spinal injuries were common in his district, and he was sure that displacement of the bones occurred and might cause paralysis. If the spine were immobilized at once many untoward symptoms would be avoided. He quoted two cases of spinal injuries which recovered after being treated by fixing the spine. He had never seen any of the secondary symptoms of concussion follow a colliery injury; he had witnessed nothing akin to the "railway spine."

Dr. Ormerod referred to the behavior of the muscles in these cases to stimuli other than blows on the tendon; the muscles reacted more readily to a direct blow than they did in normal people, the tendon reflex being absent. In one of Dr. Bastian's cases the reaction to faradism was normal; in a case of fracture dislocation at the National Hospital for Paralysis, reaction to faradic stimuli was almost absent.

The President (Mr. Timothy Holmes) said that the physiologically novel views advanced had an important bearing on treatment. In many cases the removal of the displaced bone by operation was impossible, for the displaced fragment lay in front of the cord and could not be reached. He agreed in the advisability of immediately immobilizing the injured bones.

Mr. Bowlby then replied and said that in a considerable number of cases the superficial reflexes did not return at all; in others they did so in a day or in several weeks. He laid no stress on them either for diagnosis or for prognosis; the deep reflexes alone were of value. The spinal cord in these cases could not be devitalized or the superficial reflexes would not return. He felt sure that in a large number of these cases no good could come from operation. The position he took was that when there was complete loss of deep reflexes, that then there was probably a total transverse lesion; but that when these reflexes were present the cord was certainly not completely crushed. In some of these latter cases an operation might perhaps be useful, though in the majority of them it would be of no avail. Where the column was crushed in directly from behind operation was likely to be more favorable than in those cases produced by doubling down the head.

MEDICAL LEGISLATION IN NEW YORK STATE DURING RECENT LEGISLATIVE SESSION.

To the Editor of the Medical Record.

Sir: The Governor having completed the signing of bills it may be of interest to note what measures relating to the practice of medicine or surgery have become laws.

The Medical Examination Law.—The most important law was the one establishing three boards of medical examiners. This was introduced in the assembly by Mr. Hitt, and in the senate by Mr. Chase; and it is now chapter 507 of the laws of 1890 (*vide* p. 686). In opposition to this bill, Senator Stadler introduced a single-headed medical examiners' bill which was defeated in the Senate by a vote of nine to seventeen. A bill by Senator Laughlin proposed to amend chapter 647 of the laws of 1887 in regard to the licensing and registering of physicians and surgeons and to call that act a medical act of the State of New York. This bill did not pass, some of its features having been incorporated into chapter 507 noted above. The law of 1887 provides three classes of licensed physicians and surgeons. First, graduates from medical colleges or schools in this State; second, those who have received a degree from the regents of the University; and third, those who have been graduated from medical colleges outside of the State, to be indorsed by medical colleges in this State or by the regents of the University on the recommendation of a legally constituted board of medical examiners in this State. Senator Laughlin's bill, which did not pass, proposed an additional class of licenses to all persons who shall be, at the time when this act takes effect, lawfully engaged in such practice in this State, under license or authority conferred by its laws then in force, and lawfully registered as such practitioners pursuant to chapter 513 of the laws of 1880, and the acts amendatory thereof.

Concerning Graduates from Colleges outside the State.—Senator Ives also attempted, without success, to amend the same law of 1887 so as to change subdivision 3 of section 2, relating to graduates of colleges from without the State, and make it read as follows: All, who having been graduated from incorporated medical schools or colleges without the State as doctors of medicine, or licensed to practise physic or surgery under the laws of those foreign countries in which said degree does not confer the right so to practise, or who having received the degree of doctor of medicine from a college in this State, without having passed a preliminary examination as provided in and by chapter 468 of the laws of 1889, entitled "An act to provide for the preliminary education of medical students," and the amendments thereto, shall procure or shall have procured their diplomas from said corporations or their licenses from such countries to be indorsed by the faculty of an incorporated medical school or college within this State, or by the regents of the University on the recommendation of the legally constituted board of medical examiners of this State, provided, further, that it shall satisfactorily appear to the said faculties of said incorporated medical schools or colleges, or to the regents of the University, before making said indorsement that such non-residents or applicants having a degree or diploma from medical schools or colleges without the State, or who may be licensed as aforesaid, and whose degrees or licenses shall have been conferred on and after January 1, 1891, shall possess the same educational qualifications as are required of residents within this State under the provisions of chapter 468 of the laws of 1891, and the acts amendatory thereof; every said indorsement shall be in the form of schedule "A" or schedule "B" provided by this act; every corporation or board so indorsing shall keep a record of their indorsements and may require applicants to verify their statements under oath; any indorsement made with fraudulent intent or gross carelessness, or ignorance shall be deemed a misdemeanor, and shall subject the indorser or indorsers upon conviction thereof to a fine of $250. The schedules were to be changed according to the proposed amendment.

This section of the law of 1887 was, however, amended by a law known as chapter 500, and indorsed by Assemblyman Bush, so as to add the following at the end of the third subdivision noted above: "Provided, however, that no such indorsement as is above specified shall be made until the applicant thereof shall file with the person, officer, or body above-named as authorized to make such indorsement, a certificate, signed by the secretary of the University of the State of New York, showing that such applicant has received the degree of bachelor or master of arts, of bachelor or master of science, or of bachelor or doctor of philosophy, from a college or university duly authorized to confer the same; or that he has passed an examination conducted under the authority and in accordance with the rules of the regents of the University of the State of New York, in arithmetic, grammar, geography, spelling, American history, English composition and elementary physics; or that he possesses qualifications which the regents have considered and accepted as fully equivalent to the above-named qualifications; as such degrees and certificate are more particularly defined in an act of the legislature of the State of New York, entitled 'An act to provide for the preliminary education of medical students,' passed June 13, 1889, being chapter 468 of 1889, and as the same may be hereafter amended."

Preliminary Education of Medical Students.—Chapter 499 of the laws of 1890 was introduced by Assemblyman Bush. It amends section 1 of chapter 468 of the laws of 1889, in regard to the preliminary education of medical students, so that it shall read as follows, the omitted portions of the original law being in brackets, and the portions added by the proposed amendment being in italics: Before the regents of the University of the State of New York or the trustees of any medical school or college within this State shall confer the degree of doctor of medicine on any person [who has not received a baccalaureate degree in course from a college or university duly authorized to confer the same] they shall require him to file with the secretary or recording officer of their university or college a certificate *signed by the secretary of the University of the State of New York*, showing *either* that *he possesses the degree of bachelor or master of arts, of bachelor or master of science, or of bachelor or doctor of philosophy received by him from a college or university duly authorized to confer the same or that, during or* prior to [entering upon the prescribed three years study of medicine] *the first year of his medical study within this State*, he passed an examination conducted under the authority and in accordance with the rules of the regents of the University of the State of New York, in arithmetic, grammar, geography, orthography, American history, English composition, and the elements of natural philosophy; or in their substantial equivalents approved by the said regents, *or, that he possessed qualifications which the regents considered and accepted as fully equivalent to the above-named qualifications*, [and such certificate shall be signed by the secretary of the regents and countersigned by the principal or commissioner conducting said examination].

Physicians keeping Drug Stores.—Attempts were made to amend the pharmacy act, chapter 361 of the laws of 1884, so that any person who is legally authorized to practise medicine may carry on a drug-store; also allowing retail druggists or practising pharmacists of five years' experience to receive licenses without examination. Section 11 of the law was amended, by chapter 100 of the laws of 1890, so as to make the penalties for violation of the law of 1884 a fine of not less than $25 nor more than $50, or imprisonment not to exceed six months; and a provision is made for the disposition of such fines. An unsuccessful attempt was made to amend the pharmacy law of 1884 so that country doctors may keep drug stores without a license.

A bill never reached the Governor allowing medical schools to have the same privileges that medical colleges now have in regard to obtaining bodies from penal institutions not claimed.

The Veterinary Surgeon Act of 1889 was amended by chapter 419 of 1890 so as to give until January 1, 1891 for registering those veterinary surgeons who have practised for three years without a diploma. A general law was enacted, chapter 289 of the laws of 1890, authorizing

any nine or more persons who are graduates from any legally chartered veterinary college or university, and who hold diplomas or certificates as such, citizens of the United States and of this State, who desire to form themselves into an association for the purpose of improving the methods of treating diseases and injuries of all domestic animals, to elevate the standard of integrity, honor, and courtesy in the veterinary profession, and to cherish the spirit of brotherhood among the members thereof, to sign and acknowledge before any officer authorized to take the acknowledgments of deeds in this State, and file in the office of the Secretary of State, and a duplicate thereof in the office of the clerk of the county in which such association is organized, a certificate, in writing, to be approved by a justice of the Supreme Court, in which shall be stated the name of said association, its object, the officers of the same and the names of its officers for the first year of its existence, and the name of the county or district in and for which it is formed. Such societies or associations can hold property not to exceed an annual income of $20,000. This new general law superseded a special law incorporating the New York State Veterinary Medical Society with certain veterinary surgeons of Central New York as the incorporators. It also superseded a fruitless attempt to create a State board of veterinary examiners to be appointed by the Governor, consisting of six veterinary surgeons, of which two should be the president and secretary of the New York State Veterinary Medical Society. X.

Albany, N. Y., June 10, 1890.

CONCERNING THE STANDARDIZATION OF DRUGS.

To the Editor of the Medical Record.

Sir: A wholesale dealer in pharmaceutical products some months ago advocated the principle that, as all galenical preparations depend for their therapeutic value upon certain alkaloidal or other constituents, the amount of such active elements should be made to conform to some determined standard. In other words, the preparations of drugs used as medicines should be standardized. This, it was claimed, is essential to accurate knowledge on the part of the physician of the amount of each medicinal agent to be used in a given case.

This is not a new subject. It has been studied by pharmaceutical chemists for many years; is still under consideration, and doubtless will be for years to come. Every pharmacist desires to see it accomplished, but as yet nobody—not excepting the wholesale dealer who started the present agitation of the question—knows enough about the chemistry of plants to be able to say how it can be done. There are very few drugs of which we can certainly specify the constituents in which their therapeutic activity resides; and as for the exact proportion in which these constituents should exist in the crude drug, we know probably less. The reason for this is that no two specimens of the crude drug are alike in this regard, and that we have no reliable means for extracting these constituents for examination which will insure us that the product represents all of their constituents contained by the drug; nor have we the tests which will differentiate between the various constituents of the same plant, some of which may be therapeutically active while others are inert, or have a different action. Moreover, it is believed that in plants having several constituents their relative proportions vary in nearly every case and depend upon the conditions under which the plant grows.

The so-called active principles of drugs do not exist in the plants in the forms with which we are familiar, the latter being artificial rather than natural products in many cases. There are instances in which the therapeutic action of an artificially extracted principle is quite different from that of the crude drug or its watery or alcoholic solutions.

This is a bare outline of only a few of the problems involved in the question of standardization, and I refer you for many details to a recent paper by Professor Maisch, of Philadelphia.

Very truly yours,

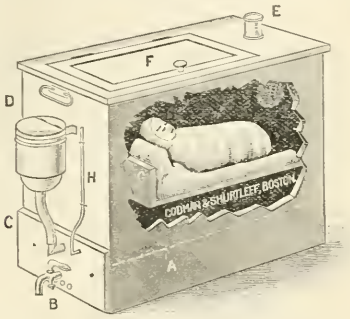
F. A. Castle, M.D.

June 10, 1890.

New Instruments.

LA COUVEUSE, FOR PRESERVING THE LIFE OF FEEBLE AND PREMATURELY BORN INFANTS.

Apparatuses for this purpose have been successfully used in Europe for a number of years, and the accompanying illustration represents one, modelled after the most perfect form, as exhibited at the Paris Exhibition in 1889.



It consists of a wooden case, 28 inches long, 23 inches high, and 17 inches wide, having a glass door (F) and ventilating valve (E) on the top, a tunnel (D), with cover, gauge glass (H), faucet (B), and ventilating openings (f) on the front, and a larger ventilator on the back (not shown). Within and at the bottom is a copper reservoir of suitable capacity (shown in dotted outline A) connected with the tunnel, also with the faucet (B). Over the reservoir is a frame with a thermostat attached for regulating the internal temperature. Above is the bed for the child, with the mattress, etc. A sponge-cup and sponge, for moistening the air, and a thermometer are conveniently placed.

When the apparatus is to be used the reservoir should first be filled with boiling water three or four hours in advance to warm it thoroughly; when the internal temperature reaches 85° to 88° F. the infant may be placed within on the bed. To maintain the temperature it is generally sufficient to add three quarts of boiling water every two or three hours, at the same time drawing off an equal quantity from the reservoir by means of the faucet, the gauge-glass (H) showing when the reservoir is filled.

The warm air rising from the reservoir escapes through the valve (E) in which turns a little helix; should the temperature within rise too high, the thermostat opens the ventilator at the back and admits the outer air until it is reduced, when it closes again. It is considered well to maintain the temperature at 86° F.

Care should be taken not to place the apparatus in a draft. The infant may be left in the couveuse fifteen days, three weeks, or even a month; then, when it has acquired sufficient vigor, it may be gradually accustomed to the outside air, first removing it into a warm room for an hour or two at a time. It is well, even then, to continue the use of the apparatus during the night for some time longer.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 8 to June 14, 1890.

STERNBERG, GEORGE M., Major and Surgeon. By direction of the Acting Secretary of War, will, in addition to his present duties, perform the duties of the post surgeon at Fort McHenry, Md., during the absence of that officer on leave.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, having been found incapacitated for active service by an army retiring board, will proceed to his home. Par. 12, S. O. 135, A. G. O., Washington, D. C., June 10, 1890.

CRAMPTON, L. W., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect the 15th instant. Par. 5, S. O. 75, Department of the Missouri, St. Louis, Mo., June 9, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending June 14, 1890.

SIMONS, M. H., Surgeon. Ordered to the Enterprise.

BEVER, HENRI G., Passed Assistant Surgeon. Ordered on duty to the Yantic.

SIMONS, MANLEY H., Surgeon. Detached from Widows' Island Hospital, and waiting orders.

HAWKE, J. A., Surgeon. Ordered to Widows' Island Hospital, and attending officers of Navy and Marine Corps at Portsmouth, N. H.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 14, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	2
Scarlet fever	63	4
Cerebro-spinal meningitis	0	0
Measles	347	25
Diphtheria	76	24
Small-pox	0	0
Varicella	7	0
Pertussis	6	0

Medical Trust. — Dr. J. V. Kendall, Baldwinsville, N. Y., writes: "That 'Medical Trust,' on p. 563 of the MEDICAL RECORD, goes to show what is often said, that 'history repeats itself,' and is, as there remarked, 'a very old scheme' rejuvenated. I have often heard my father speak of the *usual custom* in Massachusetts, when he was young [he was born in 1773] of families making an annual agreement with their physician for the necessary medical and surgical attention, in accordance to the size and circumstances of families, by the year."

A Correction.—Dr. G. W. McCaskey, of Fort Wayne, Ind., writes: "In my article on 'Disinfection during and after the Acute Infectious Diseases,' in the MEDICAL RECORD of March 1st, reference was made to the excellent work done by the Louisiana State Board of Health. The President of the Board, who had furnished me valuable information, was given as Dr. Williamson, whereas it should have been Dr. C. P. Wilkinson. Will you kindly mention the error, as it does not do justice to Dr. Wilkinson."

Leprosy in India.—Dr. Edward P. Thwing, of Brooklyn, who has been making, the past year, an extended tour in the East, gives in a concise style some observations on leprosy. "To study leprosy in its endemic seats has been my privilege in Norway, China, and India. Leper hospitals and communities at Bergen, Canton, and Colombo have presented striking clinical features of this malady, to the revival of which Sir Morell Mackenzie has recently drawn public attention. The two points around which special interest centres are its relation to syphilis and its alleged contagiousness. In India it is estimated there are about a quarter of a million lepers. Bengal, with about the same population as the United States, has 54,000 lepers, and the single city of Calcutta 1,200. The Colombo community, visited a few weeks since, during ten days' stay at Ceylon, has more than a century's history. The monogram of the daughter of a colonial governor, herself a leper, founder of the hospital, was shown me. It bore the date 1708. Early records are wanting, but W. A. Kynsey, M.D., now in charge, is an intelligent observer and careful compiler of all facts bearing on the characteristics of the disease. His community of 208 lepers has an area of 16 acres, high, wooded, yet airy and sunny, on the northern side of the Kelani River, an hour's ride from the city. There are 14 wards and 14 servants. Everything is scrupulously neat. The floors of the spacious brick buildings are cement, with ground as well as roof ventilation; Venetian doors and other oriental appointments, as dry earth latrines. The sexes are separated. Two chapels are provided, one for Protestant natives, and one for Romanists, and also a school for children, besides Buddhist instruction for those who choose it. The population of the western provinces of the island, from which this hospital is supplied, numbers 897,329. Two-thirds of the cases are of the anæsthetic type. The scant attire of Tamil and Singhalese gave excellent opportunity for inspection in this, the best clinical lecture on dermatoses ever enjoyed. The patients are of all ages and about equally divided as to sex. They did credit to the excellent hygienic and dietetic system of treatment followed, and were lounging about the wards or on the veranda, breathing the perfume of 'Ceylon's spicy isle,' apparently contented. The disease is ordinarily painless, but a patient is always exposed to intercurrent maladies—diarrhœa, fevers, ulceration of the colon—and to acute attacks of leprosy, when eruptions of a livid hue appear on the body and limbs, behaving like boils. 'Pruritus is sometimes so very painful,' says Dr. Enders, of Molakai, 'sufferers in their agony will tear out pieces of flesh with their nails.' I first saw a man sixty years of age, the oldest patient, twenty-five years a leper. His children are apparently untainted. It is not safe to predicate immunity so long as life lasts. A Borneo boy, in sport, pricked a leper on an insensate area of the body, and then himself with the same knife. In nineteen years he developed leprosy. The period of incubation varies. This patriarch of the asylum, to whom I was first introduced, has facial paralysis and ataxic gait. The lower jaw drops and his saliva oozes, reddened with betel-nut which he chews, making a hideous appearance. He stretched out both hands, stiff and distorted. The epidermis is peeling off. Cellular degeneration and other complications mark the retrograde metamorphosis of the tissues. Lardaceous deposits and fibrous hypertrophy attend the onward course of the disease. The central system, in this case, does not yet share the disability of the peripheral. He takes an interest in everything, and seems to suffer no acute pain. The next man was younger, in the prodromal stage, without the macular and other characteristic pigmentations which attend chronic conditions. In leprosy, as in syphilis and other chromatogenous diseases, the varying condition of the blood-pigments as a whole, or in their distribution, records itself on the skin. With interrupted nutrition and neuritis, white hairs appear in leucodermic patches, or melanoderma, as in Addison's disease, and following syphilitic roscola. I photo-

graphed a leper in Benares, illustrating color changes, as well as marked alopecia. Another feature, familiar to specialists, was shown in a third and a fourth case, the adherence of the eruptions to the nerve-tracts, the median and ulnar nerves particularly. Dr. Kynsey expressed no opinion of his own as to the kinship of leprosy and syphilis, but wished me to note the eversion of lip and nose, nodules on the chin, and suspicious epithelial appearances, with absorption of septum in some patients. Arabian authors quoted by Vidal classed the two together. He thinks that the use of mercury for both, four hundred years ago, is a proof of kinship, though each has now been so specialized. 'The part that lepra plays in the production of these (syphilides) has been reduced to so small a compass that it would seem no longer to exist.' Erasmus Wilson puts lepra and psoriasis in the same category, and says that syphilitic leprosy and syphilitic psoriasis are the product of the 'almost universal poison, syphilis.' Dr. Van Holsh, of Guiana, Dr. Enders and others, of Honolulu, believe that 'leprosy is the offspring of syphilis,' and their experience is extended. Among Colombo lepers, I saw one peculiar case where elephantiasis was added to leprosy. The left leg was of huge size. Interstitial absorption from the distal extremities of the toes had taken place. In others the absence of hair from the eyebrows, the deadness of finger-nails, and chronic œdema of the legs were observed; induration of the tissues of elbow and knee, tuberculous scars on breast, back, and abdomen, as if cicatrized, raised above the skin, and rough, beaded, ragged helix, frequent bruises or burns of portions of the body which have lost sensation, and from these festering sores. Some showed a decay at the proximal end of a toe or finger with spontaneous amputation. In Bombay one or two cases were seen where this doubtless has been the course. Vision is lost toward the end in some cases, and in two, the past two years, asphyxia occurred, when the velum of the larynx was involved. Sex did not differentiate diagnostic signs. Uterine functions are not interrupted, unless with climatic or other complications. The face of one woman showed ridges like branding burns, while the usual turgid and nodular appearance of the alæ nasi was marked. Erythematous affections of the plantar surfaces of the feet and palmar surfaces of the hands; also furunculoid eruptions as in syphilis, angry, obstinate, and painful; glandular tenderness and rheumatic pains; exfoliation of bone with serpiginous patches, often gyrate or necklace like, mark the progress of disease. Of 600 cases treated, Dr. Kynsey had obtained no evidence of contagion, yet he acts on the assumption that leprosy is contagious. No mercury is used. Food and sanitary measures are first in importance. Salicylic acid and tonics, carbolic oil, and inunctions of gurjan and chaulmoogra oil have yielded good results. Segregation is insisted upon. In the community I visited at Bergen the same general treatment prevails. There has been a decrease of forty-five per cent. in twenty-five years in Norway, since the policy of isolation has been insisted on by government, in face of the ill-considered deliverance of English physicians in 1867."

Kentucky State Medical Society.—The thirty-first annual session of the Kentucky State Medical Society was held at Henderson, Ky., May 14, 15, 17, 1890. The President, Dr. J. A. Ouchterlony, of Louisville, was in the chair, and the Secretary, Dr. Steele Bailey, of Stanford, was at the desk. The Hon. John L. Dorsey delivered the address of welcome. Dr. A. Dixon read a report on the progress in surgery. The President read his address on the early practice of medicine in Kentucky. Dr. G. Frank Lydston, of Chicago, made an address, "Materialism *vs.* Sentiment, in the Study of the Causes and Correction of Crime." The following officers were elected: *President*—Dr. George W. Beeler, of Clintonton; *Senior Vice-President*—Dr. J. M. Poyntz, of Madison; *Junior Vice-President*—Dr. Ap Morgan Vance, Louisville; *Permanent Secretary*—Dr. Steele Bailey, of Stanford; *Assistant Secretary*—Dr. J. Y. Oldham, of Lexington; *Treasurer*—Dr. J. B. Kennard, of Lancaster; *Librarian*—Dr. T. B. Greenley, of West Point. The next place of meeting is Lexington, and Dr. David Barrows, of that city, chairman of the committee of arrangements. Delegates were chosen to the National and the International Conventions. At the banquet at the Barrett House, toasts were responded to as follows: "Kentucky State Medical Society," Dr. John A. Ouchterlony, of Louisville. "State Board of Health in Prevention of Disease," Dr. Pinkney Thompson, of Pembroke. "Art in Medicine," Dr. J. M. Matthews, of Louisville. "Philanthropy in Medicine," Dr. G. Frank Lydston, of Chicago. "The Ladies," Dr. L. S. McMurtry, of Louisville. "Medical Press," Dr. Dudley S. Reynolds, of Louisville. A ball was given at the Armory in honor of the doctors, and was very enjoyable. A profusion of Kentucky feminine loveliness added its charms to the occasion. The address of the President of the Kentucky State Medical Society was made by Dr. J. A. Ouchterlony, of Louisville. He took for his subject "The Pioneer Medical Men and Times in Kentucky." The noble adventurer who first in 1747 plunged bravely into that pathless wilderness known as "the dark and bloody ground," was a medical man, Dr. Thomas Walker, who had married a cousin of George Washington. The first practising physician in Kentucky was Dr. George Hartt, at Harrodsburgh. The first surgical operation was done by Colonel James Smith, and was done on himself, in the wilderness, and with no one but a mulatto boy with him. Colonel Smith was not a medical man. Mrs. Frances Coomes, the wife of William Coomes, was the first lady physician. She was physician, surgeon, and obstetrician, and renowned in all. She was, according to tradition, the first to make bread or salt in the State. Among her posterity is a member of this society, Dr. M. F. Coomes, of Louisville. Dr. H. McMurtrie wrote, in 1819, the first history of Louisville, and discussed geological and philanthropic matters. He also has a descendant in the person of Dr. L. S. McMurtry, an ex-president of this Society. The first medical book was published by Dr. Thomas W. Ruble, in 1810. The first medical society in the State was established in Louisville in 1819. A doctor's bill dating from 1780 shows that Dr. Harft charged Mr. Clews $240 for eight doses of calomel, and $240 for four blistering plasters. Among the early operations are two of excision of the pancreas, in 1816. Biographical sketches were given of Dr. Frederick Ridgley, Dr. John Milton Harney, Dr. Walter Brashear, and Dr. Theobald. Dr. Arch Dixon, of Henderson, read a report on the progress in surgery. He made a comparison of the surgery of past years with that of to day, and laid special emphasis on the use of antisepsis in the treatment of wounds. Laparotomy, intestinal and brain surgery, and the radical cure of hernia were carefully discussed. "Gunshot Injury of the Spine, with Paralysis; Death after Four Years," was the subject by Dr. M. E. Alderson, of Ressellville. He presented the specimen showing the ball projecting into the spinal canal from the vertebræ where it was embedded. "Two Cases of Ectopic Gestation, cured by Abdominal Section," was the subject of a report by Dr. A. C. Bernays, of St. Louis. The first case reported was the first case of early operation for ectopic gestation successfully done in the State of Missouri. The examination of the specimen showed an exquisite hæmato-salpinx due to a tubal pregnancy, the blood having escaped from the villi of the chorion at the point where the placenta was developing. The tube is distended so that it is two and a half inches in its largest diameter, and three and a half inches long. The surface of the tube is covered by shred-like adhesions, although in some places the peritoneal covering is seen in a normal condition. The muscular coat of the tube is much hypertrophied, averaging an eighth of an inch in thickness. The embryo was not found, but traces of it were seen in the shape of translucent gelatinous tissue, lying within

the clot, which filled the tube. The second case was found in syncope, after a ruptured ectopic pregnancy. This is a case where the patient's life was undoubtedly saved by prompt surgical interference. The pregnancy must have been between seven and nine weeks' duration. In many respects the case was an instructive one, and the doctor thinks it the first case of ruptured interstitial gestation which was saved by abdominal section.

Society of the Alumni of Charity Hospital.—At the meeting of the Society of the Alumni of Charity Hospital, held May 13th, Dr. H. H. Hagan presented a case of multiple angiomata in a child of two years. There were about thirty of the tumors, situated on the head, face, body, and extremities. Dr. Clement Cleveland showed an interesting specimen—a very much thickened Fallopian tube, removed from a patient suffering from chronic pyosalpinx opening into the colon. The tube was so much thickened as to be mistaken for the ovary. Dr. W. L. Carr read a paper on "Laryngismus Stridulus," which gave rise to an animated discussion.

A Double Monster.—There is now on exhibition a double monster, known as the Tocci Brothers. The children are thirteen years of age, and were born of an Italian woman living in humble circumstances. The body as far as the shoulders is single, but is double above. The stomach is common to the two children, and if one eats heartily the other has no desire for food, yet it is said that the two are very unlike in their appetites and tastes, one being fond of sweets, while the other cares only for substantials. The genital organs are male, but the face of one of the children is very feminine in its appearance.

The Action of the Positive Pole of the Constant Current upon Pathogenic Bacteria.—In a paper read before the Academy of Sciences of Paris, a report of which we have received through the courtesy of Dr. Horatio R. Bigelow, Drs. Apostoli and Laguerrière reported the results of a series of experiments made by them to determine the action of the constant current upon microbes. Their previous experiments had led them to conclude that, 1. The action of the constant galvanic current upon cultures is in indirect proportion to its strength, measured in milliampères. 2. Other things being equal, for the same intensity the question of the duration of the application is of no value, the intensity of the current being the chief factor. 3. A current of 300 milliampères or more, applied for five minutes, always kills the bacteria of charbon. Cultivations made with the culture so treated remain sterile. 4. A current of 200 to 250 milliampères, applied during five minutes, does not always destroy the virulence; some of the snakes inoculated with such cultures died, but more slowly than those inoculated with cultures which had not been exposed to the action of electricity. 5. A current of 100 milliampères or less, even after an application for thirty minutes, does not destroy the virulence; it produces an attenuation which increases with the force of the current. Since the experiments upon which these conclusions were based were made, the authors have found that these effects are independent of the thermic action which accompanies electrolysis. They have since then also studied the individual action of each pole, and have formulated these supplementary conclusions: 1. By suppressing the calorific effects of the current it is possible to obtain destruction and attenuation of the vitality of the germs. 2. The positive pole alone kills or attenuates pathogenic organisms, over which interpolar action of that or the negative pole has no control. 3. The antiseptic action of the positive pole (in the midst of a culture entirely separated from the negative pole) takes places with even smaller doses than when the two poles are close to each other. The positive pole does not kill with 50 milliampères during a period of from five to thirty minutes, but the attenuation of the virulence of a culture so treated increases progressively. The general conclusion drawn from these experiments is that the continuous current of the usual strength used in medicine (50 to 300 milliampères) has no action upon cultures in a homogeneous medium, and that the peculiar action of the positive pole is due to the disengagement of acids and oxygen.

Hysteria following Typhoid Fever.—Professor Grasset, of Montpellier, has recently recorded a well-marked instance of this condition occurring in a girl, twenty three years of age, who until then had shown no sign of hysteria. She had passed through a mild attack of typhoid fever and was convalescent, and allowed to get up daily, when she was suddenly attacked with complete paraplegia. This was considered to be "hysterical" in character because of the coexistence of the following symptoms: A number of persistent stigmata, incomplete left hemianæsthesia, absence of the pharyngeal reflex, and contraction of both fields of vision. A month later complete aphonia was developed. The diagnosis of hysteria was verified a few days later by the patient suddenly recovering her voice and the power over her legs, so that in a few days she was able to leave the hospital in perfect health. A similar case is quoted from Trousseau. A patient of his, twelve years of age, was attacked with paraplegia during convalescence from typhoid fever, and all treatment was without benefit, until one day she was accidentally locked in her bedroom. When the nurse returned she found the patient standing at the door, having walked without much difficulty from her bed to try to open it. In neither of these cases had there previously been any tendency to hysteria.—*The Lancet*, April 26, 1890.

A Case of Sporadic Cretinism.—A case of this interesting disease is described under the name of "idiotic myxœdemateuse," in the current number of the *Archives ae Neurologie*, by M. Bourneville. The patient, who is now twenty five years of age, is the youngest of five. None of the others are cretins, but several have died of tuberculosis. The parents were not related, and the mother was quite healthy, but the father died of phthisis. Until three years of age the patient is said to have talked, walked, and played just like other children; but at this time he stopped growing and became fat and puffy. On his admission to the Bicêtre his height was only thirty-five inches and a half, and his weight fifty-four pounds. His head was bossy, with projecting occipital region, and his anterior fontanelle was not quite closed. His forehead was low, narrow, and compressed laterally. There was the usual thickening of the eyelids, so that they could scarcely be raised at all. The teeth were irregular in position, and the temporary canines and premolars had not been shed either in the upper or lower jaw. There were the usual masses of fat seen on each side of the neck, and no thyroid gland could be detected. There was general thickening of the skin, and very great development of adipose tissue in front of the abdomen and in the gluteal regions. The genital organs were those of a young boy; there was no tendency to masturbation. The patient was able to feed himself, although slowly. He was unable to read and write, and his language was confined to a few monosyllables. If he used a longer word, he pronounced only the last syllable. He was fond of sewing, which he did fairly well, but he was quite unable to dress or undress himself. He was fond of smoking, and apparently affectionate, but usually appeared indifferent to surrounding circumstances. The case is of interest in the late development of the symptoms. In a case shown at the Clinical Society by Dr. Abercrombie, myxœdema was set up at the early age of eight, after some obscure acute illness, which he suggested might possibly have been an acute inflammation of the thyroid gland, leading to its atrophy. The information as to the onset in this case was not complete, as the parents could not be questioned, but it is just possible that this may have had some similar origin.—*The Lancet*, April 26, 1890.

A THEORETICAL AND PRACTICAL DEMONSTRATION OF THE ACTION AND TENSION OF THE TENDO-ACHILLIS IN SUPPORTING THE BODY ON TIPTOE.[1]

By WILLIAM E. WIRT, A.M., M.D.,

HOUSE SURGEON, HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

Several years ago my attention was drawn to this subject by a lecture delivered by the late Dr. Sabine, on the action of the tendo-Achillis, in which the tendon was represented as acting on the foot in the simple manner in which the power acts in a lever of the second class, thus sustaining the weight of the body, the power being represented as a weight and pulley, the cord passing over a wheel as seen in Fig. 1.

In this demonstration the reaction of the power W (W representing the tension on the tendo-Achillis) is taken up by the pulley P. This is not so in sustaining the body on tiptoe, in which latter case the reaction is down through the tibia CA. I have since noticed, in the writings of authors who treat of the action of muscles, that much the same form of demonstration is applied.

My attention was again called to this subject at the January meeting of the Orthopædic Section, New York Academy of Medicine, by a criticism made to Willett's operation for shortening the tendo-Achillis in infantile

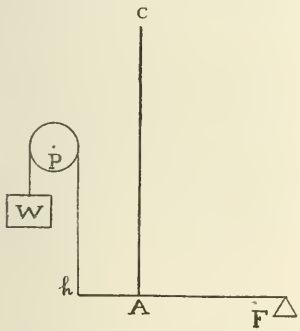

Fig. 1.—C, Calf, or point of attachment of muscles to tibia; F, Fulcrum (ball of foot); h, Heel (attachment of tendo-Achillis); W, Weight (represents power in calf muscles); A, Ankle; P, Pulley.

paralysis; the objection being that the tendo-Achillis had to sustain a number of times the weight of the body, and in its weakened condition the tendon could not sustain this tension. The mechanism, in the demonstration, was regarded simply as a lever of the second class.

Instead of the foot and ankle being a simple lever of the second class, thus following its simple laws, it partakes more of the quality of a mechanism in which there is considerable loss of power, due to the force acting at a disadvantage, *i.e.*, the force acting in one direction being opposed by its own reaction as transmitted in a slightly different plane, plus the weight of the body.

In raising or supporting the body on tiptoe at any given angle, the moments of the forces raising the heel h, or turning the foot hF around the fulcrum F in an upward direction, must be equal to the moments of the forces bearing down through the tibia CA and tending to turn the foot hF in the opposite or downward direction around the fulcrum F. The moment of the force tending to raise the heel is T, the tension on the tendo-Achillis multiplied

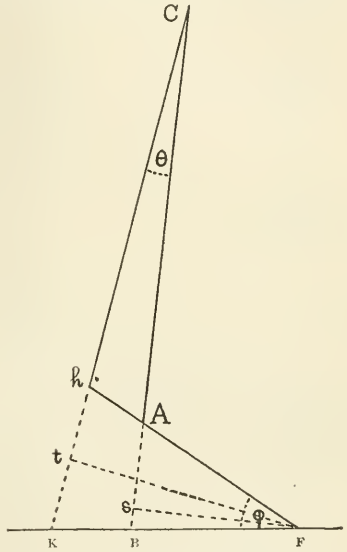

Fig. 2.—W, Weight of body; T, tension on tendo-Achillis; C, mean point of attachment of calf muscles to tibia; A, ankle; F, fulcrum (ball of foot); h, attachment of tendo-Achillis; Ft, perpendicular to direction of tendo-Achillis; SF, perpendicular to direction of tibia; θ, angle which tendo-Achillis makes with tibia; Φ, angle which sole of foot makes with ground; ΦO, at instant when foot leaves ground; KF, surface of ground.

by Ft, the perpendicular drawn from the ball of the foot to the line of direction of the tendo-Achillis. The moments of the forces bearing downward through the tibia are:

1. The reaction of T, the tension of the tendo-Achillis as transmitted to the foot through the tibia. This reaction (R) is equal to T cos θ; and the moment of this reaction R is T cos θ, multiplied by SF, the perpendicular drawn from the ball of the foot to the line of direction of the tibia.

2. The weight of the body (W) bearing downward through the tibia; and its moment is W multiplied by AF cos ϕ.

Now we have seen that moments in the different directions must be equal; therefore we have the equation.

$$T \times Ft = T \cos \theta \times SF + AF \cos \phi \times W$$
$$T \times Ft - T \cos \theta \times SF = W \times AF \cos \phi$$
$$T (Ft - SF \cos \theta) = W \times AF \cos \phi$$
$$T = W \frac{AF \cos \phi}{Ft - SF \cos \theta}$$

To determine T from this formula we must calculate by trigonometry the values of Ft, Fs, θ, and ϕ; and to do this we must know accurately the values of hF, AF, CA, and the angle CAF, the angle formed between the tibia and the foot, and the angle CBF, that between the tibia and the ground. The latter quantities (hF, AF, CA, etc.)

[1] Read before the Orthopædic Section of the New York Academy of Medicine, March 21, 1890.

I determined by measurements on the several members of the staff of the Hospital for Ruptured and Crippled, and the former quantities (Ft, FS, θ, and ϕ) by trigonometrical calculations. The following is the result for different positions of the foot:

		Angle CAF.	Angle θ.	Angle Φ.	sF (inches).	tF (inches).	T.
Dr. Logue.							
CA=16 in. AF=5¼ in. Ah=2¼ in.	Foot about horizontal.	82°	7° 16′	0°	5.20	7.217	2 542W
	Extreme tiptoe...	165°	2° 25′	75°	1.359	2.245	1 53W.
Dr. Fitzhugh.							
CA=15 in. AF=4 in. Ah=2¼ in.	Foot about horizontal.	82°	8° 17′	0°	3.961	6.200	1.925W.
	Extreme tiptoe....	160°	3° 26′	70°	1.368	2.485	1.221W.
Dr. Wirt.							
CA=16 in. AF=4¾ in. Ah=2⅜ in.	Foot about horizontal.	80°	8° 31′	0°	4.677	6.874	2.112W.
	Extreme tiptoe....	153°	4° 43	63°	2.156	3.811	1.30W.
Dr. Depass.							
CA=17 in. AF=5 in. Ah=2½ in.	Foot about horizontal.	83°	8° 12′	0°	4.965	7.25	2.236W.
	Extreme tiptoe....	165°	2° 55′	75°	1.31	2.21	1.434W.
Average.							
CA=16 in. AF=4¾ in. Ah=2⅞ in.	Foot about horizontal.	82°	8° 11′	0°	4.701	6.835	2.20W.
	Extreme tiptoe....	161°	3° 22′	71°	1.548	2.688	1.37W.

The values of T, the tension on the tendo-Achillis given in this table, were found by substituting values of SF, tF, AF, θ, and ϕ, in the formula $T = W \frac{AF \cos \phi}{Ft - SF \cos \theta}$.

We see by the table that the average value of T when the foot is just leaving the ground is 2.2W, and in extreme tiptoe T = 1.37 W. Also, that the higher the foot is raised on tiptoe, the less is the tension on the tendon. Nevertheless, it is not easier to stand in this position than in a less elevated one; for, the more a muscle is contracted, *i.e.*, the nearer the origin and insertion of a muscle are brought together, the less powerful is the muscle. On examining this formula, we see that when $\phi = 90°$ then $\cos \phi = 0$, therefore T = O. That is, when the foot is held vertically on tiptoe, the tension on the tendo-Achillis is O. This, we see, would be in accordance with the facts. But this is a theoretical position, as one cannot ordinarily balance one's self in that position.

Dr. Judson exhibited, at the March meeting of the Orthopædic Section, New York Academy of Medicine, a mechanical contrivance so arranged that a horizontal bar represented the foot, a vertical bar the tibia, and a spring balance scales attached to the upper end of the tibial bar and the heel end of the horizontal bar represented the calf muscles forming the tendo-Achillis, and also indicated the tension brought to bear upon it. A bag of shot attached to the upper end of the vertical bar represented the weight of the body. The vertical bar had a hinge motion upon the horizontal bar, and could be adjusted at different distances between the heel and toe end. By an attachment to upper end of vertical bar the centre of gravity could be so shifted that the apparatus would balance with the foot-piece at different angles to the ground. When the apparatus was balanced on the toe end (having been so arranged that the foot-piece would remain about horizontal), and the vertical bar was hinged at twice the distance from the toe end as from the heel, *i.e.*, the same relation the tibia bears to the ball of foot and the heel, the spring balance registered 2+, or a very little more than two times the weight of the bag of shot, which agrees exactly with my calculations as given in the tables. When the apparatus was balanced with the foot-piece at different angles, the scales registered values of T ranging closely to those given in the table.

But the above values of T are on the supposition that the tendo-Achillis has the whole weight of the body to lift.

Henry Morris, in his "Anatomy of Joints" (p. 409), gives the following muscles as the elevators of the heel, viz., muscles attached to tendo-Achillis, tibialis posticus, flexor longus pollicis, flexor communis digitorum, and peroneus longus. The latter four muscles are together, in size or quantity of muscle, about $\frac{2}{3}$ that of the muscles forming the tendo-Achillis, and their contractile power is about in this proportion.

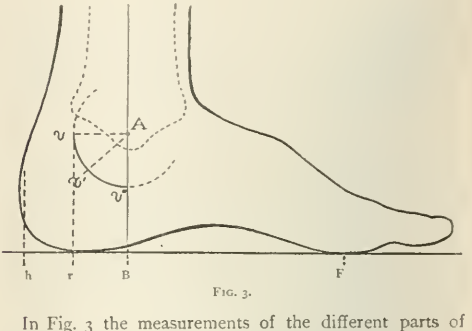

FIG. 3.

In Fig. 3 the measurements of the different parts of the foot are the average as calculated in the tables:

BF = $4\frac{3}{4}$ in. Br = Av = $1\frac{1}{2}$ in. Bh = $2\frac{3}{8}$ in. hr = $\frac{7}{8}$ in. qAB is the axis of the tibia and passes through A, the axis of flexion at the ankle. The dotted lines represent the contour of the tibia. The tendo-Achillis while relaxed arches forward, due to the elasticity of the fascia and skin; but when made tense, as in supporting the weight of the body, it passes in nearly a straight line to the muscles of the calf.

The four deeper muscles named above, viz., tibialis posticus, flexor longus pollicis, flexor communis digitorum, and peroneus longus pass behind the malleoli, around the astragalus and os calcis, along the arc v v' v'', and are attached to bones of the anterior and middle part of the foot. In their mechanical effect to lift the heel they act as a cord passing around a wheel. With A as an axis they act on a radius Av of $1\frac{1}{2}$ inch. Or considering F, the fulcrum, as the fixed point, the muscles act on the radius Fr = $6\frac{1}{4}$ inches (= $4\frac{3}{4} + 1\frac{1}{2}$).

In order to have equilibrium established we must have, as in the case of the tendo-Achillis, the forces in the different directions around F equal. (The reaction of T as felt at A is so nearly equal to T in this case that it may be called T.) Therefore:

$$T \times Fr = (T + W) \times FB; \quad T = W \frac{FB}{Fr - FB}$$

$$= W \frac{4.75}{1.5} = 3.1W.$$

For every unit of weight lifted by this group of muscles 3.1 units of power are required, while for the tendo Achillis only 2.2 units of power are required per unit of weight.

To apportion off the work between the two sets of muscles so that each shall do its proportional amount, requires that it be divided in the ratio of the amount of muscle in each group, modified by the effective power of that group.

Let X = proportion of body weight sustained by tendo-Achillis.

1 − X = proportion of body weight sustained by other posterior muscles.

Then

$$X : 1 - X :: \tfrac{2}{3} \times \tfrac{1}{2.2} : \tfrac{2}{3} \times \tfrac{1}{3.1}.$$

Solving this equation we have $X = \frac{1}{10}$. That is, the tendo-Achillis is only required to lift $\frac{1}{10}$ the weight of the body, the other $\frac{9}{10}$ being sustained by the deep group of posterior muscles.

The tension (T) on the tendo-Achillis would be .7 W × 2.2 = 1.54 W.

Therefore the tension on the tendon is 1½ time the weight of the body when the foot is just leaving the horizontal position, and rapidly diminishes as the foot is raised into extreme tiptoe, being only ½ the weight of the body in the latter position, when the deep muscles are considered. (Foot raised to 161°.)

THE TREATMENT FOR THE RADICAL CURE OF POLYPI OF THE NOSE.

By E. HARRISON GRIFFIN, M.D.,

ATTENDING SURGEON OF THROAT AND NOSE DEPARTMENT OF BELLEVUE HOSPITAL OUT-DOOR POOR, NEW YORK.

In operating for the removal of polypi of the nose, we have the choice of three different methods. First, injecting each tumor with some irritating fluid, and allowing the growth to slough; second, by the forceps; and third, by the snare. The first method is liable to be tried on account of its simplicity, but it will soon be abandoned, as it takes weeks to destroy one of these growths by this method of procedure.

This operation is attended with great pain, and if there are a number of polypi the time taken up in the operation is considerable, and the after-result is not satisfactory.

This leaves two remaining methods, the forceps and the snare.

The only reason I can see for the employment of the forceps is that it can be used by anyone, while the snare requires a certain amount of dexterity that takes a little time to acquire. In operating with the forceps we are liable, at the first introduction of the instrument into the nasal cavity, to wound and tear the membrane; the hemorrhage that follows will so obscure the polypi that further operation will be conducted entirely in the dark. We cannot penetrate to the pedicle of the growth as readily as with the snare. The forceps takes a polypus out in sections, while the snare can remove the whole growth, with its pedicle, in the majority of cases, especially if it is a virgin case upon which we are operating.

I have enumerated the three methods of operating, as the manner in which the polypus is removed is an important factor in the question whether it will return.

The injection of the polypus is impracticable. The forceps cannot remove the growth as completely as the snare, the wire of which can be nursed to the attachment of the growth to the turbinated bone, while the thickness of the bit of the forceps prevents this procedure.

I consider an operation with the forceps brutal and unsurgical.

I have operated for the last two years with the little instrument illustrated in Fig. 1, below.

It is a modification of Dr. Bosworth's snare, but it is much stronger and the wire is more easily fastened by the

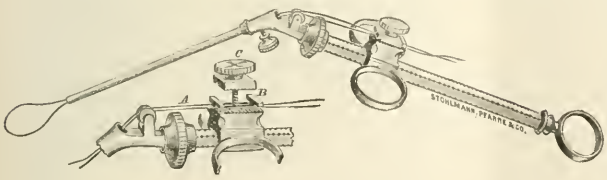

Fig. 1.

little clamp *C*, than by the pin attachment on the former snare. The wire, after passing through the cannula, runs over a small pulley *A*, and then through a fine slot *B*, and can be attached firmly to the instrument by lowering the screw *C*.

The instrument in my hands has effected most satisfactory results. I have no trouble in guiding the wire around the growths, and in most of my operations securing the root of the polypus.

This snare can also be used in posterior hypertrophies of the inferior turbinated bone. A curved attachment is also made, so that the wire can be carried to the vault of the pharynx in search of adenoid vegetation.

No matter how thorough the operation has been, a small pedicle is liable to be left somewhere embedded in the membrane of the turbinated bone, and if this is not destroyed it forms the root of future polypi.

Three or four years ago I treated the nose with a strong solution of chromic acid after I had thoroughly removed all the polypi in sight, so that the whole contour of the turbinated bones was visible, and the nasal cavity showed absolutely no nasal obstruction. Later I tried carbolic acid, tincture of iodine, and actual cautery, with the idea of destroying any pedicle that had escaped the wire. If the case had been operated upon previously by the forceps, the growths were sure to return and the operation of removal resorted to again.

The application of caustics or the actual cautery does not prevent the return of polypi. They only inflame the part to which they are applied, and tend, I think, to the formation of new-growths.

I have taken a case and removed thoroughly the growths from both sides of a nose. To one side I have applied a caustic, the other I have let pass without after-treatment. In watching this case I have found that the side I cauterized duplicated the growths more quickly than the side that had passed without treatment. I have tried this experiment in a number of cases, and the result is always the same.

Lately I have abandoned entirely the cauterizing after removal of polypi, as I think it causes inflammation and a quicker reproduction of the growth.

Before operating with the snare, I try first to put the parts under complete control of the cocaine, or, in other words, the parts must be thoroughly anæsthetized. I consider this a most important factor in the operation. First, as the cocaine empties the blood-vessels of the turbinated tissue and allows a more nearly perfect view of the growths; and second, because, when the part is under the influence of the drug, the hemorrhage is more perfectly controlled, and the irritation resulting from the introduction of the snare greatly diminished.

In looking at a nose filled with polypi, a concrete mass is the only object that can be seen. We are unable to distinguish one polypus from another, but with the aid of cocaine the mass seems to subdivide and each individual polypus is easily seen. Cocaine has thus greatly augmented the per cent. of permanent cures. I would never attempt to operate till the parts were entirely free from sensation. No pain should be felt during the operation, no matter how slight, as pain in this case is significant of irritation, and this we should studiously avoid if we aim at the permanent destruction of the tumors.

A case that has been operated upon previously by the forceps is more difficult to cure radically than a case that presents itself in a virgin state.

This clinical fact has been impressed upon me again and again, both in the Bellevue clinic and in private practice. The forceps seems to tear the growth away and to spread the roots, so that the polypus has a broader attachment and becomes more of a sessile growth, while a virgin polypus has a root as small as a thread, as shown in the illustration.

Fig. 2 represents the tumor at its present size, after being in alcohol for over two years. It hung between the soft palate and the pharynx, and was attached to the middle turbinated bone.

In a case previously operated upon by torsion, the attachment is much broader and the roots of the polypi more dispersed.

In removing these growths we should aim to produce as little irritation as possible, and after the operation the same condition of affairs should still be preserved.

Any irritation, in my mind, will lead to a recurrence of these growths. I have seen this so fully illustrated by the application of caustics and cautery, that I was led to abandon their use entirely after polypus operations, and seek for some other medication that would prevent tumors from reasserting themselves. I do not know how many astringents I have used with this aim in view. After a thorough trial of almost everything in the Pharmacopœia in the way of an astringent, I have abandoned all medication, with the exception of witch-hazel or the application of pure alcohol. To the former I give the preference.

Fig. 2.

After a thorough search for remaining polypi and their removal, I have the patient spray the nose night and morning with either of the above-mentioned drugs, diluted at the start with water and gradually increased to full strength, by means of a Burgess spray. The parts should be thoroughly moistened with the chosen drug, so that it floods the nasal fossa and runs into the lower pharynx.

This treatment should be persisted in steadily for at least a year after the last remaining polypus has been removed. The nose should be examined at stated intervals, and if there is a semblance of a polypus it should be removed.

I copy from my note-book a report of a few obstinate cases that have been treated with the cautery and caustics after the polypi have been thoroughly removed, and then afterward with the witch-hazel. With the cautery treatment the polypi returned, but with witch-hazel medication the return of the growth rarely occurs. I might add that most of my obstinate cases for the permanent destruction of these growths have previously been operated upon by forceps.

Case I.—M. C—— applied to me, complaining of polypi of the nose. She had been operated upon repeatedly, for this affection, by the forceps. The operations were very painful and attended with profuse hemorrhage. I removed fully three hundred polypi from her nose at various sittings. At the end of each series of sittings, the lumen of the nose was perfectly restored and the contour of the turbinated bones easily seen. At this time, as at the present time, cauterization after removal of polypi was the customary treatment.

In succession I tried chromic acid, glacial acetic, carbolic, tannic, actual cautery, and the tincture of iodine, and, in fact, any medication that would permanently prevent these growths from re-forming.

These astringents irritated the parts, and I found that the polypi returned more quickly when I was seeking to destroy them by that means than when I left after-treatment alone. Failure after failure with these agents led me to try a new drug. This case I treated, after removing the large number of polypi before mentioned, with the spray of witch-hazel, night and morning, and was surprised to see the return of the growths wonderfully diminished.

The patient has been free from these growths now more than a year.

Case II.—Female, had been operated upon repeatedly, by the forceps, by another practitioner. Acid was applied after the operation. The polypi quickly returned. I removed twenty polypi from this patient's nose, put her under the witch-hazel treatment, and the polypi have not since returned.

Case III.—Male, aged forty. Had polypi of the nose from the age of twenty. The nose had been "cleared" regularly every six months, and the caustic applied after each series of sittings. The patient was accustomed to go to a physician at these stated times to have the growths removed. After clearing his nose thoroughly of the offending bodies, I put him under the hamamelis spray. Eighteen months have passed without a return of the growths.

Case IV.—Mr. A—— applied to me for a diagnosis of his case. His nose had been stopped up for years. Acid had been injected into a few polypi, but the pain and time experienced in this mode of procedure led him to abandon treatment for a period. When he applied to me, I found his nose completely obstructed. I removed over a hundred polypi from the nasal fossa in a week. This was in June, 1888. I saw him again January, 1889, and removed six. In August he paid me another visit. I found one side of his nose perfectly free, the side I had not cauterized, while from the other I removed four polypi. I consider this an excellent report of a case where the operations followed in such quick succession, and so long a time elapsed between visits.

A thorough removal of polypi cannot be secured at one sitting, or at a few successive sittings. When we remove the lower strata of the growths, the one above drops down, and the nose may appear after a few operations to be the same as at the first one.

Time should be allowed for the polypi to descend, as the pedicle is more easily detached, the irritation less, and the hemorrhage much diminished. *Festina lente* is a good adage, in the removal of these growths, for a permanent cure.

I could cite case upon case where the polypi have returned after removal, with the after-treatment by caustics. The only remedy I have been able to secure to prevent their return has been either witch-hazel or some preparation of alcohol, as a local medication, after their total and thorough removal.

I do not claim that the injection of witch-hazel or alcohol into a nose filled with polypi, or one partially filled with the tumors, will extirpate them, but what I do maintain is, that for a perfect cure of the troublesome affection—1, the nose should be treated with the snare till each and every polypus has been removed; 2, that the after-treatment by caustics and cautery tends to inflame the cavity, and tends to the recurrence of these growths; 3, that in the removal of these tumors the parts should be so thoroughly anæsthetized that pain is unknown, because when pain is absent the part is under the full influence of cocaine, the blood-vessels are relieved of their congestion, the polypi are more easily distinguished, and the main object of the operation is secured, removal of the pedicle intact; 4, that the part should be sprayed thoroughly with either witch-hazel or alcohol, for some time after the patient has been pronounced free from all polypi; 5, that with this treatment the majority of cases can be permanently cured, and the rest greatly relieved.

112 West Forty-fifth Street.

Opium-Smoking in London.—Some startling facts are brought to light by a writer in a recent issue of the *Medical Press*, concerning the increase in the habit of smoking opium in London. A gentleman who had been told that this habit was growing, determined to make some inquiries himself. After some time he learned that application for information should be made to a certain well-known medical practitioner, living in the West End. The gentleman's wife wrote to this practitioner, asking information, and received in reply a copy of a pamphlet entitled, "Opium Smoking as a Therapeutic Power, according to the Latest Medical Authorities." The pamphlet describes in detail the method of preparing and smoking the opium, and recites the conditions which are said to be specially benefited by taking the drug in this form. The physician who is supposed to be the author of the pamphlet is himself a confirmed opium-smoker, and he seems to be actuated with a desire to drag others down to the level of his own degradation.

THE TREATMENT OF THE[1] ACUTELY INSANE IN GENERAL HOSPITALS.[1]

By W. P. SPRATLING, M.D.,

FIRST ASSISTANT PHYSICIAN NEW JERSEY STATE ASYLUM FOR THE INSANE, MEMBER OF THE NEW YORK MEDICO-LEGAL SOCIETY.

THIS is a question concerning the treatment of this especial class of the insane that has lately sprung into prominence, and one that bids fair to create a general and liberal discussion, as its nature warrants and justifies. In no branch of medicine, or in any of the allied sciences that tend to promote the universal welfare of a people, have such marked advances been made in recent years as in the study and treatment of psycopathic disorders, and the very suggestion of any new feature that will have a tendency to place round about the insane such environments or influences as will the better aid him to recovery, or make his life during the term of confinement less burdensome, will meet at once with a candid and wholesome discussion at the hands of those whose lives have been spent in endeavoring to ameliorate the condition of this unfortunate class. This question appeals alike to medical, scientific, and men of philanthropic ideas, for each one of these find in the insane man some especial interest, and something that claims the skill and sympathies of each.

The primary consideration of this question by those who form the foremost rank and file of able and humane alienists of to-day will doubtless engender but one reply; and it would be difficult to convince these, with any argument short of actual demonstration, that the acutely insane could be more successfully treated in general hospitals than in asylums as at present. On their part it would virtually be to disclaim the knowledge of insanity they had been acquiring all these years, and a renunciation of progressive ideas, practical reforms, and methods instituted by themselves. It would be to acknowledge themselves as "latter-day drones," so to speak, and, by their own assertions, unfit to work longer in this great field of labor. The present happy and increasing enlightenment, great or little as it may be, that dawns more clearly upon us each day, throwing here a gleam, and flashing there a ray of light upon some hitherto dark and mysterious problem, springing from the diseased human brain, and the care of the individual possessing it, is due to those who have studied this malady in all its phases in the many great asylums now existing, so nobly founded by public charity, and whose internal management is so ably and humanely administered through the light of increasing knowledge. To bring about such a change in the custodial care and treatment of those afflicted with the acute types of insanity, can only be done by the sanction, and with the authority, of the State's law-makers. Legislation on this subject should not be hastily enacted; for so radical a change, affecting, as it most assuredly would do, the character of all general hospitals into which insane cases might be admitted, and robbing existing asylums or hospitals for the insane of the very cases the State intended these institutions should receive, deserves a careful and extended consideration. At the January meeting of the New York Neurological Society of the present year, a committee, consisting of Dr. Frederick Peterson, Dr. Chas. L. Dana, and Dr. Ralph L. Parsons, was appointed to examine and report upon a revised code of lunacy laws, known as the Gallup Lunacy Bill. This bill, the year before, passed the New York Legislature, but failed to become a law on account of the Governor's opposition to it. Portions of this bill were favorably, and other portions unfavorably reported upon by the committee, and among other recommendations they made the following: "A clause should be introduced into the bill providing that nothing in the lunacy laws of the State shall be construed to interfere with the reception and treatment of acute cases of insanity in chartered general hospitals, in the same manner and under the same conditions as patients suffering from other diseases are there received and treated, provided such hospitals have suitable accommodations approved by the State Commission in Lunacy."

In the *New York Medical Journal* of February 22, 1890, appears an editorial in which is reviewed the work done by the committee appointed by the Society to examine into the merits and demerits of the Gallup Lunacy Bill, and the writer of this article, in referring to the clause advising the reception of the acutely insane into general hospitals, says: "In our opinion this is the most valuable portion of the committee's report, for it suggests a step forward in the line of a great reform." Then, at some length, the author comments upon the unsatisfactory form of treatment he assumes such cases to receive at the hands of those charged with this responsibility in our great asylums; and some of the criticisms embodied in this paper are unfair and unjust, being so clearly from the fact that the writer is evidently not well informed concerning the details of internal management that prevail in most of our State institutions of to-day. Moreover, it is not alone in this particular that a lack of information is evident, but when, as the writer of this article says: "The insane are no longer to be regarded in the light of insane criminals, and asylums are not always to bear the stigma of existing as a species of jail," he shows the fact that this idea, at one time prevalent, but long ago discarded as barbaric by all men who studied the true cause and character of a man's madness, is overlooked by him, and to-day, if there be a stigma affixed to any man's name who has ever been of unsound mind, it is by those who are untutored and ignorant regarding the inherent nature of this unfortunate malady.

The admission into general hospitals of cases of acute insanity cannot be done under the confident expectation of having them regain their reason in from "three weeks to three months," as the writer says. Very true, many acute cases, which at the outset appear extremely unlikely to recover, get well in three months, or in a shorter period of time. But just in proportion as this number of favorable cases, as regards an early recovery, will require admission, a yet larger number will be admitted whose acute attack will not terminate in a few weeks or months, but pass into a chronic hopeless one, and in the course of time, for many apparent reasons, their removal to a regular hospital for the insane becomes necessary. In the article above referred to, it is stated that upon admission into an asylum "a patient's personality is entirely lost in the horde of from six hundred to two thousand mad people among whom he is placed." It is true that some overcrowding in many of our hospitals for the insane exists to-day, but it has been unavoidable, chiefly on account of the great increase in the number of insane. The evils of confining too large a number of insane under one roof has been ably shown by American alienists in late years, and the magnificent institutions that are being built to-day upon that most excellent and scientific plan known as the cottage system, is actual proof of their wise recommendations.

But let us consider for a moment one of our ordinary State asylums, or hospitals for the insane, that has not many of the important improvements that institutions of a later growth enjoy; and let us go for a moment with a case of acute insanity, as he is sent from the reception-room to one of the hospital wards. Here he finds himself one of a number of from twenty-five to twenty-eight patients on a ward that, in point of size, could comfortably accommodate from thirty-five to forty. Here he can be provided with a single room, if it be deemed advisable. Here he is seen twice daily by an assistant physician, and the fact that he is on the hospital ward entitles him to the same physical treatment, as well as mental, that he might receive in any general hospital. In regard to the treatment or actual medication of the insane, the writer of this article, in speaking of acute cases in asy-

[1] Read before the New York Medico-Legal Society, May 14, 1890.

lums, says, "Does he disturb others? Then narcotize him. If that be impossible, put him into the pandemonium known as the back ward." If we have not in our asylums to-day all known means of quieting the maniacal frenzy common to madmen, if it be best for him and those around him, then surely there is no potent charm or conquering influence that can be used as so happy a benefactor in any general hospital. Another most important consideration in regard to this proposed new method should not escape notice, and that is the effect of the admission of such cases upon the public character of a general hospital and the local reputation it enjoys. It cannot be denied that general hospitals, through the ever increasing efficiency of the service they offer in caring for the bodily sick and injured, are coming daily into more popular favor, and a large number of such cases, by their own choice, are admitted into these hospitals for the purpose of being treated therein. Recognizing, then, the indisputable fact, that general hospitals are steadily increasing in public patronage, it is fair to assume that a knowledge by patients, who, be they the subjects of public charity, or paying individually for what they receive, are equally solicitous as to their surroundings, and of the fact that madmen were being cared for under the same roof as themselves, would have upon them an unsalutary effect. Public opinion on questions that have for their underlying principle the comfort and welfare of communities is an unmarketable article, and one that cannot be disposed of except in such a manner as will satisfy the greatest number entertaining such opinions. This very fact is undoubtedly responsible for the removal from the city of one of the best known and most thoroughly equipped asylums in this country.

Again, we find in this article the assertion that, if the acutely insane were admitted into general hospitals under the same conditions precisely as other patients are received, it would lead to a "vast improvement" in the early and efficient treatment of the nutritive disorder of brain. I must confess that I am unable to realize how the creation of this vast improvement is to be brought about, and what the method of its application is to be. A person sick in a crowded city, with even a physical disorder that has been created more from the monotonous routine of his form of business and social life, the ever-recurring daily scenes and the constant excitement of busy traffic, is advised by his physician to seek some secluded spot, some remote abiding place in the country or on the sea-shore, where nature can substitute the charm of her inspiring impressions upon his tired senses for those fatiguing scenes and confining occupations that have well-nigh made him a physical wreck. Why not let the unfortunate and penniless poor of the city who may fall a victim to some acute mental disorder be taken from such surroundings and placed out in the country in suitable homes provided for them, where wholesome winds blow and the noise of traffic is unheard. Concerning the reception-houses in New South Wales and Queensland, and of lunacy wards in Victoria for the treatment of insanity in ts early stages, nothing can at this experimental period of their existence be said in favor of such methods that would justify their adoption in this country. The construction of a psycopathic hospital that is about to occur in London is indeed a noble conception, and one embodying, as it will, every known scientific method and means that present knowledge can devise in the treatment of the insane, will doubtless bring incomparable good to all who must partake of the beneficent and scientific skill that is to be found within its walls. Yet at the head of the internal management of this hospital is to be placed a "resident medical officer of asylum experience," and with him he carries, as his chief qualification for this high office, the very knowledge of insanity previously acquired in asylums with which he must have been connected. For some time past an undercurrent opinion, generated in the minds of some of the most progressive and ablest psychologists in this country, has been in existence, in which the idea embodied is the abolition of the word asylum, as it is applied to places in which the insane are treated. In the third annual report of the St. Lawrence State Asylum for the Insane at Ogdensburg, N. Y.. Dr. P. M. Wise, the Superintendent, says: "I would further recommend at this time a change of the present title of the asylum to the St. Lawrence State Hospital, to accord with the higher function of the institution, as herein set forth. The patients in an institution are confronted with the name at all times, and it has an influence in creating impressions greater than is generally known." For suitable reasons he furthermore says: "Neither is it necessary to attach the word 'lunatic' or 'insane' to the title." The managers of that institution concurred with Dr. Wise in his opinion, and by an act of the Legislature recently the name was changed to the St. Lawrence State Hospital.

Dr. Edward Cowles, Superintendent of the McLean Asylum, near Boston, also refers to this subject in his last annual report. In speaking of a new building that is to be erected at Belmont for the inmates of McLean Asylum, he says, "It is not a new asylum we want; it is a new hospital."

Dr. G. Alder Blumer, Superintendent of the State Lunatic Asylum at Utica, N. Y., in his last annual report, writes at some length upon the "Hospital Idea," in the course of which he says: "In my last annual report I ventured the suggestion that a change of the name of our State Lunatic Asylum to State Hospital would be desirable, as better showing the character of the institution, and serving to impress upon the public the fact, so continuously ignored, of the physical basis of insanity, and all that that simple doctrine implies." Among all the desirable changes that present and future conceived enlightenment on the subject of insanity brings to us to-day, none seems of more vital importance than the abolition of the word asylum, and with it, if possible, its linked associates "lunatic" and "insane." These words, I doubt not, have in some instances, isolated though they be, been the Gibraltars upon which the feeble hope of some oversensitive minds, distorted by disease, have been dashed to their death. To me it seems a matter of most vital importance, for I believe it to constitute a rational and humane step forward in the line of a truly great reform. Worcester defines asylum as a "sanctuary, a place of refuge, a place of retreat and security; a shelter, originally applied to places in which criminals and debtors were secure from arrest." Webster defines asylum to be "a sanctuary; or place of refuge and protection, where criminals and debtors were secure from arrest; and from which they could not be taken without sacrilege. In later times Christian churches were regarded as asylums in the same sense. So sacred was the church to some that it had the right of an asylum or sanctuary." In the dark ages this might have been a suitable definition for a place in which those were confined who were thought to "be possessed of an evil spirit," but to-day science, coupled with liberal knowledge and truly humane ambition, should seek to abolish this misnomer, and not relax its efforts until it has accomplished its great aim.

In view of the foregoing, Mr. President, I beg to offer this resolution:

Whereas, Insanity is now generally conceded to be a physical disease, and, as such, a malady for medicinal treatment, as much so as inflammation or fever;

Resolved, That this Society commend the adoption of the term "hospital" in place of "asylum," for institutions having the care of the insane.

MORRIS PLAINS, May 20, 1890.

Beer should not be Drunk from Glasses, according to Dr. W. Schultze, who has discovered that they contain lead oxide, and that a small amount is dissolved by the CO_2 in the beer. This is one of the cases in which Dr. Schultze has saved at the spigot but leaked at the bung. There are things in beer which kill long before the lead.

Clinical Department.

A NORMAL ANUS WITH THE RECTUM ENDING IN A BLIND POUCH.

By F. F. C. DEMAREST, M.D.,
PASSAIC, N. J.

On May 28th I was called at night to attend Mrs. J——, a primipara, aged twenty-two, and delivered her, with forceps, of what seemed to be a perfectly normal male child, weighing nine pounds. The mother and child both did well. On one of my visits the nurse called my attention to the fact that the child's bowels had not moved. Upon a digital examination I was surprised to find that my finger, after passing through the anus, was in a cul-de-sac one inch in depth, which ended as a membranous partition below a closed rectal pouch. I at once determined upon a protoplastic operation, and with the very kind assistance of Drs. Terhune and Carroll, of this city, I was able to dissect down to the rectal pouch, and, bringing it down to the external sphincter, attach it there by interrupted sutures, and then remove the end of the gut.

After evacuating a large amount of meconium the parts were cleansed, the rectum plugged, and a gauze compress applied to the external wound. The little patient has suffered from no complications, and is now nursing and sleeping well, and performing his bladder and rectal functions normally.

CRANIAL COMPRESSION AS A FACTOR IN INFANTILE DISEASES.

By THOMAS S. BLAIR, M.D.,
CHAMBERSBURG, PA.

In perusing a volume upon midwifery, written in 1824, by Professor Wm. P. Dewees, I have been impressed by the author's cautious recommendation of the obstetric forceps as used to compress the fœtal head in cases of retarded delivery. I desire to direct attention to a passage from this volume, in connection with a case lately under my observation.

Dr. Dewees said: "It has been imagined, from the elongation which the head sometimes permits in long protracted labors that it would bear with impunity any compressing force which might be applied. . . . I must, then, to prevent the perpetuation of this error, as far as may be in my power, declare, that the head will bear with safety but a moderate diminution of its bulk by the compressing force of the forceps; and oftentimes, much less than is sometimes observed to take place, when the child has been delivered solely by the exertion of the natural powers." In Professor Theophilus Parvin's late work almost equally conservative statements are made. Authors who are specialists in obstetrics always direct attention to the immediate dangers to the child from the use of the forceps, while they are apt to overlook the remote ones observed in general practice.

Now for my case. Mrs. F——, a healthy American woman, was delivered of a male child by the use of the forceps in the hands of an experienced obstetrician, after labor had been vainly progressing for sixty hours. When the child was five months old I was called "to cure his spasms." I found the usual symptoms of inflammation of the brain, and noted a marked ridge over the coronal suture, and, on the right side of the head, the remains of an old scalp wound which the parents stated was due to a severe injury made by the forceps, and which was very slow in healing. The little patient gave evidence of great pain whenever this portion of the head was pressed upon, and strong pulsation could be detected at the fontanelles. Spasmodic action of the flexors of the left arm, and particularly of the left thumb, as also similar manifestations of the left facial muscles had been noted by the parents for months, and it was generally regarded as an indication that the child would be left-handed. They also stated that the child was rapidly losing flesh, vomited frequently, and seemed to suffer from severe attacks of headache. While under my care he had scores of clonic spasms, which differed much in severity but were invariably confined to his left side and obstinately resisted treatment. The pupil of the left eye was more or less constantly dilated, and there existed the alternating chills and high fever usual in septic infection. I was unable to definitely locate the position of the abscess, which I felt sure existed somewhere in the right hemisphere. Much to the surprise of the parents, I prognosed death in from four days to a week. The patient rapidly went into a semi-comatose condition, and the heart pulsations finally became too rapid and irregular to control with drugs, and he died in six days. Just as he expired a quantity of pus and serum broke through the ethmoid into the nasal cavity. I regret that a post-mortem was not permitted.

As is well known, the various neuroses, and particularly abscesses in the brain, may for a long while have scarcely any symptoms, and this is particularly true of those insidious and ill-defined abscesses developing after apparently insignificant injuries of the head. Were the matter carefully looked into, I believe that cranial compression in cases of forceps delivery would be found to exercise a greater part in the etiology of various diseases in infants than is usually attributed to it. At all events, a wise conservatism should control us whenever we are prompted to use the forceps to compress the fœtal head.

EARLY MATERNITY.

Dr. T. B. Nichols, of Plattsburg, N. Y., writes: "In a woodchopper's shanty, in the winter of 1855, dwelt two brothers, French Canadians, whose wives, also French Canadians, were sisters. That winter was not half passed when the writer was called to attend the youngest one in childbirth. The labor was normal and of short duration. The child was a plump six-pounder, and healthy in every respect. As the doctor was gathering up his hat and things to leave, the brother-in-law asked, 'Say, doctor, how old do you think that little mother is?' 'I should say about fifteen years.' 'No, sir,' said he, 'she is not thirteen yet.' And I can add that among that class of people in those days early maternity was not an uncommon occurrence."

Right-sided Hemiglossitis.—Dr. Joseph Leidy, Jr., reports the following case of this interesting affection in the *University Medical Magazine* for May, 1890: I. M——, aged twenty-eight; single; born in Poland. Five days before admission had a slight chill, with fever. He soon after noticed his tongue was slightly swollen upon the right side, which rapidly increased, until the organ protruded from the mouth, and interfered with deglutition and respiration. On admission to hospital he had a temperature of 101⅘° F.; pulse, 86; respiration, 24. His lips were slightly cyanosed, his expression was anxious, and he complained of some pain on pressure. The tip of the tongue protruded toward the affected, or right, side. The swelling was limited entirely by the median line, extending backward to the root. The organ was slightly coated, and saliva flowed constantly from the mouth. As there was no point indicating the presence of pus, and his symptoms were not markedly urgent, a mercurial purge was administered, with a wash of borax for the mouth, and his condition was carefully watched. The swelling rapidly diminished, so much so that by the next morning he could close his mouth perfectly, and a week afterward the act of swallowing was but slightly impaired, all the swelling had disappeared except for some slight induration at the root of the organ, somewhat painful upon deep pressure. This, however, rapidly subsided, and the patient soon felt so much better that he insisted upon leaving the house. Ten days after his admission his temperature was normal and his tongue clean, but when protruded the tip still pointed slightly to the affected side.

MEDICAL RECORD:

INGERSOLL ON VIVISECTION.

COLONEL INGERSOLL'S large capacities for unbelief have taken in the practice of vivisection, which he recently places in the same category with Moses and the Prophets. In a letter to a Boston gentleman the distinguished rhetorician calls vivisectionists "scientific assassins;" he asserts that human sympathy and sense of justice are higher than all discoveries and inventions; furthermore, Colonel Ingersoll, though agnostic, knows as follows:

"I know that good for the human race can never be accomplished by torture. I also know that all that has been ascertained by vivisection could have been done by the dissection of the dead, or, at least, of animals completely and perfectly under the merciful influence of ether. I know that all the torture has been useless. All the agony inflicted has simply hardened the hearts of the criminals without enlightening their minds."

The Colonel adds: "Never can I be the friend of one who vivisects his fellow-creatures. I do not wish to touch his hand. When the angel of pity is driven from the heart, when the fountain of tears is dry, the soul becomes a serpent crawling in the dust of the desert."

This sounds well, although as a matter of fact serpents do not crawl in deserts; but ignoring this slight concession of the truths of natural history to the demands of oratory, the eloquent writer continues:

"The wretches who commit these infamous crimes pretend that they are working for the good of man, that they are actuated by philanthropy, and that their pity for the sufferings of the human race drives out all pity for the animals. They slowly torture them to death, but those who are incapable of pitying animals are, as a matter of fact, incapable of pitying men."

Now, if the "fur" be removed from all this entrancing rhetoric, we find it amounts simply to the statement that vivisectionists are all "criminals," "assassins," and "torturers," and that their work has been utterly valueless to humanity. Or, if anything has been achieved, it might have been done in other ways.

This plain condensation of Colonel Ingersoll's long argument shows how densely and inexcusably ignorant of the whole question the new apostle of the anti-vivisectionists is.

It would be interesting, in the cause of history and ethics, to compile a list of Ingersoll's "assassins, criminals, and torturers," so called. Chief among them, doubtless, would be William Harvey, who was, to be sure, thought in his day to have been a modest, kind, and generous man, but who begins his work announcing his great discovery, "Ex vivorum dissectione, qualis sit cordis notus." Among the "torturers" and "assassins" of the last century would be Galvani, Haller, and John Hunter. The nineteenth century list would include the heretofore renowned names of Sir Charles Bell, Marshall Hall, Magendie, Bernard, and later of a dozen great men, with each of whom no taint of viciousness or personal cruelty has heretofore ever been associated. One can fancy Mr. Ingersoll refusing to shake hands with the late Professor Dalton, or the happily still living Weir Mitchell, because these amiable gentlemen were so depraved in character!

As for the question whether vivisection has been the means of securing great and useful advances in knowledge, it is settled beyond all doubt or peradventure. We have repeatedly been over the recorded list of practical discoveries. They are accessible to everyone, and, considering this fact, it is worse than ignorance, it is a culpable knavery, which puts forth such utterly false statements as those of Ingersoll's.

Mr. Ingersoll says "I know," but he does not know about what he writes. He has been at pains to tell the world why he is an agnostic. We can help to the solution. It is because he does not inform himself, as other and more conscientious people can and do.

The discovery of the circulation of the blood, of the functions of the spinal nerve, of the action of galvanic currents, of the localization of brain functions, the use of the ligature, the discovery of the bacterial causation of disease and the modes of prevention, the methods of inoculations against rabies and anthrax, the improvement in surgical methods, the action of many important drugs have been learned through vivisection.

Mr. Ingersoll's specialties are, we believe, law and religion.

"Ne sutor ultra crepidam."

THE SORE-THROAT OF SCARLET FEVER.

MM. BOURGER AND WURTZ, of Paris, have recently made interesting investigations regarding the nature of the pseudo-diphtheritic angina of scarlet fever. The cases were observed in the Hôpital Trousseau, where a number of children were suffering from scarlet fever with severe diphtheritic angina. A bacteriological examination of the membranes showed in all the cases the presence of the streptococcus pyogenes, either alone or associated with other microbes of suppuration. In two cases only did they find, late in the disease, the specific bacillus of diphtheria, *i.e.*, the bacillus of Löffler.

The patients were in three instances infected from the diphtheric wards.

The authors conclude that in the great majority of cases the scarlatinous angina is not of a diphtheritic nature.

The Massachusetts Medical Society held its 109th annual meeting in Boston on June 10th and 11th. The annual dinner took place on June 11th, under the chairmanship of Dr. Joseph Stedman, and was a most enjoyable affair. Dr. A. L. Loomis responded to the toast complimentary to New York

News of the Week.

The Manhattan Hospital.—There has recently been trouble at the Manhattan General Hospital over the hospital rules, the Board of Managers insisting that they be obeyed to the letter. To this the two senior members of the house staff objected, especially as one of the rules provided that the house surgeon should tell the superintendent where he was going when he went out. This resulted in the house surgeon and his senior assistant sending in their resignations, to take effect at once. For the last two weeks the junior assistant has been doing the entire work alone. The trouble was settled at the meeting of the managers a short time ago, when the old rules were given up entirely, and the rules of the New York Hospital adopted. A house surgeon will be employed, at a salary of $50.00 per month, to serve till November 1st next.

Tickets of Membership to the Berlin Congress.—We have received several communications from gentlemen who state that they forwarded their fee for membership in the Congress, but failed to receive the ticket. It was announced that all who sent five dollars to Dr. Bartels would receive their ticket and a programme of the meeting two months or so in advance of the opening of the Congress, and it was urged that this be done in order to avoid the crowd in Berlin. The sole reply to the advance of five dollars has been a postal card receipt, which must be presented in Berlin before the ticket can be obtained. We fail to see the advantage gained by those who have sent their entrance fee in advance. They have had the trouble of forwarding the money, and must still elbow their way through the crowd in Berlin in order to obtain their tickets. It is a small matter, but the managers of the Congress ought not to make promises unless they intend to keep them.

How to Get Lodgings at Berlin.—A special committee has been formed which will furnish all desired information as to lodgings, etc., to the foreign visitors in Berlin. Inquiries should be addressed to the office of the Congress, 19 Karlstrasse, Berlin, N. W., the envelope being marked on the outside "Wohnungsangelegenheit."

Decline of the Small-pox at Milan.—The *Gazetta Medica Lombarda* of recent date reports that the epidemic of small-pox, which has been prevailing during the past fall and winter at Milan, is now practically at an end. Nevertheless, the work of vaccination and revaccination proceeds, and the vaccination committee announces that it is in a position to meet all demands for vaccine material by return of post. The committee states that its stores of vaccine were replenished three times in the course of 1889, by material obtained from outbreaks of cow-pox in calves at Locate-Triulzi, in the province of Milan, in the public slaughter-house of the city of Milan, and at Cosio, in the district of Valtellina.

Bernhardt and the Dose of Chloral.—A telegram states that Sarah Bernhardt nearly killed herself recently by taking an overdose of "chloral." The overdose was 120 grains, which is really not a very dangerous dose to an adult, and especially to one accustomed to its use. A dose much above 120 grains, however, becomes most serious, and 150 grains taken at once is usually fatal. It is somewhat curious that Bernhardt should have taken exactly the maximum safe dose, and that the amount should be so carefully stated. If the dose had been much less people would not have been interested; if it had been much more she would not have been believed. Bernhardt is a great artist.

The Orange County (N. Y.) Medical Society held its annual meeting in Goshen on Tuesday, June 3d. The following officers were chosen for the ensuing year: *President*, Dr. Arthur Pell, of Goshen; *Vice-President*, Dr. W. L. Cuddeback, of Port Jervis; *Secretary*, Dr. B. Pillsbury, of Middletown; *Treasurer*, Dr. H. H. Robinson, of Goshen.

The Census Questions.—The Pennsylvania State Board of Health has issued a circular urging upon physicians the desirability of filling out the blanks sent them from the division of vital statistics. Dr. Lee, Secretary of the Board, states that the Superintendent of the Census guarantees that all information furnished on the schedules will be considered and treated as strictly confidential, no names being published. We fail to see how such an assurance can affect the ethical side of the question. The attempt to collect the statistics desired will fail in its object, and ought never to have been made.

The Oregon State Medical Society held its seventeenth annual meeting on June 10th, 11th, and 12th, at Portland, Ore. The Portland physicians gave a banquet to the visiting doctors from other portions of the State. The meeting was very successful, and the following officers elected for the ensuing year: *President*, Dr. G. M. Wells, of Portland; *Vice-President*, Dr. W. E. Rinehart, of the Dalles; *Secretary* and *Treasurer*, Dr. C. C. Strong, of Portland; Dr. Canthorn was elected a member of the Executive Board.

St. John's Guild.—The summer trips of the Floating Hospital will begin early in July, and will be continued four days each week, if sufficient funds be contributed. The managers appeal to the public for a generous support of their undertaking, in order that as many children as possible may receive the benefits of the Floating Hospital and Sea-side Hospital. Checks may be sent to Charles Schwacofer, Treasurer, 21 University Place.

Complaints against the Steam-Heating Company.—Inspectors from the Board of Health are investigating the causes of the several explosions of the pipes of the New York Steam-Heating Company which have occurred lately. The company has been complained of as a common nuisance, and detrimental to life and health.

Jack, the Ink Slinger.—A curious form of monomania has appeared in the city here recently. A quiet and apparently respectable married man developed a fondness for throwing ink on women's dresses, particularly on pretty dresses. He would follow his victim along the street and when a favorable opportunity arrived throw the ink, which was concealed in a pipe, upon the dress. More than fifty cases of spoiled dresses were reported before the man was discovered. He was promptly condemned to six months in the penitentiary. He is a monomaniac.

A New Hospital in Nashville.—Bishop Rademacher has purchased the building formerly occupied by the Nashville City Hospital, and will make extensive additions before reopening it. When the repairs are completed the hospital will be placed under the care of Catholic Sisters. This makes the third church hospital established recently in Nashville.

The Rhode Island Medical Society held its 79th annual meeting in Providence on June 11th. The election of officers for the ensuing year resulted as follows: *President*, Dr. John W. Mitchell; *First Vice-President*, Dr. William H. Palmer; *Second Vice-President*, Dr. Robert F. Noyes; *Recording Secretary*, Dr. William R. White; *Corresponding Secretary*, Dr. George D. Hersey; *Treasurer*, Dr. George L. Collins.

A Home for Nurses.—A movement is on foot in Brooklyn to erect a house to serve as a home and hospital for the trained nurses of the city. It is intended to be self-supporting, as is the nurses' house in Boston, which is under the auspices of the Guild of St. Barnabas for nurses.

The Delaware State Medical Society began its second century on June 13th, at its 101st annual meeting in Wilmington. The election of officers resulted in the choice of the following: *President*, Dr. Joshua A. Ellegood, of Laurel, Sussex county; *Vice-President*, Dr. Ezekiel Cooper, of Camden, Kent county; *Secretary*, Dr. W. C. Pierce, of Wilmington; *Treasurer*, Dr. Joseph H. Chandler, of Centreville.

Guarding against Yellow Fever.—The Norwegian steamship Adria, from Boca del Toro, with fruit, arrived at the New Orleans quarantine station on June 21st. Her cargo of bananas was removed to barges and the vessel fumigated and sent to the lower quarantine station. The health authorities report that the steward of the Adria died while *en route* to the Passes and was buried at sea, and one of her crew is ill with fever, a suspicious case, but not yet pronounced yellow fever.

St. Joseph's Hospital, Hamilton, Ontario, was formally opened on June 11th. It is under the care of the Sisters of St. Joseph, but any patient admitted to it may select his own physician, as well as his spiritual adviser if he should desire one.

Fire in a Hospital.—Mercy Hospital, in Davenport, Ia., was partially destroyed by fire on June 11th. One of the Sisters was lost in the flames. The damage to the building and its contents will amount to about ten thousand dollars, which is nearly covered by insurance.

The Cholera in Spain.—Fewer cases of cholera have been reported in Rugat during the past week, but the disease has spread to a number of other villages in the province of Valencia. The baggage of all travellers arriving in Madrid from the infected district is disinfected before being delivered to its owners, and Morocco has established a quarantine of five days on all vessels arriving from Spanish ports on the Mediterranean. Portugal also quarantines all vessels arriving from ports in the infected district, and the Italian government has urged upon the health officers the need of a rigorous examination of all arrivals from the Spanish coast.

The Maine Medical Association held its annual meeting in Portland, on June 10th, 11th, and 12th. The following officers were elected: *President*, Dr. S. B. Hunter, of Machias; *First Vice-President*, Dr. B. B. Foster, of Portland; *Second Vice-President*, Dr. F. L. Dixon, of Lewiston; *Corresponding Secretary*, Dr. O. W. Stone, of Camden.

Reinstating the Religious in France.—The French radicals have made an extensive trial of lay nurses in the hospitals of Paris, and have been forced to admit, much against their will, that the change was not for the better. Now the process of restoring the Sisters has begun, and at a recent meeting of the Paris Municipal Council a proposal for the reinstatement of the Sisters of Mercy in the municipal hospitals was carried by 41 out of 61 votes.

The Canadian Medical Association.—The next meeting of the Canadian Medical Association will be held in Toronto, Tuesday, Wednesday, and Thursday, September 9th, 10th, and 11th. The Committee of Arrangements appointed at the last meeting at Banff has been largely increased in numbers and is now thoroughly organized under the chairmanship of Dr. Canniff. There were at first differences of opinion as to the best time for holding the meeting, but after careful consideration it was unanimously resolved to hold it early in the first week of the Toronto Industrial Exhibition.

Dr. James Murphy, of San Francisco, died in that city on June 7th, hepatic disease being the cause of his death. He was born in Ireland, and was graduated in medicine from the Pacific Medical College in 1862. He leaves a wife and three children.

A Sponge in the Abdomen.—In one of the Milwaukee hospitals an abdominal section was performed early in this month. After the sutures were all in place and the wound was dressed, one of the nurses called attention to the fact that a sponge was missing. Thorough search was made without success, and it was not until the abdomen was reopened that the sponge was found. The patient recovered. A similar accident occurred in the same city about three years ago, the subject being a sailor who had been shot in the abdomen. He was taken to the hospital and the intestinal wounds were closed. He died, however, and at the post-mortem examination a sponge was found in the abdomen. The man could not have recovered in any case, and the sponge could not be held accountable for his death.

Moderate Charges.—A physician of San Francisco recently sent in his bill to the estate of a rich but penurious man who had died under his care. He charged for his visits at the rate of $100 each, and the total amount of the bill was over $3,500. As the physician had some distance to go to see his patient the charges would not seem to be absurdly high, but the public administrator nevertheless cut down the amount to $1,100, and will resist in the courts the payment of any sum above this.

Dr. Helen L. Webster, of Lynn, who has recently been lecturing at Bernard College, and who has been called to a chair at Vassar, is one of the three women in America who have received the degree of Ph.D., "summa cum laude," from the University of Zurich.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

RETENTION OF URINE CAUSED BY A HYDATID CYST—THE TREATMENT OF PHTHISIS BY THE INHALATION OF SUPER-HEATED AIR—THE GRIEVANCES OF HOSPITAL NURSES—THE GENERAL MEDICAL COUNCIL.

LONDON, May 30, 1890.

At the last meeting of the Clinical Society, Dr. Fairbank read an account of a case of retention of urine in which a hydatid cyst in the pelvis was found to be the cause of the condition. The patient was a man aged sixty-five, who had suffered from repeated attacks of retention, and on whom at last a catheter could not be passed. A trocar was passed *per rectum* into what was supposed to be the bladder, when four ounces of opaline fluid escaped. It was then found possible to pass a catheter *per vias naturales*, and about a quart of dark-colored urine was drawn off. A second cyst, under the abdominal wall in the left iliac region, was aspirated and proved to be a hydatid. Six months later, the patient passed with his urine several hydatid cysts; four of these were examined and were as large as ordinary walnuts partially collapsed. The patient had been examined lately (after ten years), and there were no signs of either the iliac cyst or of that between the bladder and the rectum.

Mr. W. H. Bennett remarked that cases of this kind were rare, though hydatid cyst was often mentioned as one of the causes of retention of urine. A patient of his own—a man aged fifty—had apparently a distended bladder which, however, was not reduced in size by catheterization. He, therefore, punctured *per rectum*, and withdrew three pints of hydatid fluid, sp. gr. 1.006. The cyst did not shrivel, so he laid it open from the rectum and drained it for a week; it discharged for six months, but could not be felt now. Mr. Bennett remarked that in one recorded case death had been determined by pressure on the ureters, and in another the cyst ruptured into the rectum.

Among the other papers read at the same meeting of the Society was one by Mr. H. H. Taylor, on the treatment of phthisis by the inhalation of super-heated air. Only four cases thus treated had been under his observation, two of them being cases in which there was laryngeal as well as pulmonary phthisis. In all the results were negative. The inhalation of air at 300° F. apparently caused no inconvenience; neither the temperature, pulse, nor respiration was affected, nor did the skin act more freely. Two cases of pulmonary cavities, which had been tapped and drained, were made use of in order to determine, so far as possible, whether the heated air extended beyond the bronchi. The communication between the air-tubes and the cavities was, in each case, very free, but after the inhalation of air at 300° F. a thermometer placed in the cavity only rose one degree in one case, and in the other case no rise of temperature whatever took place.

Attention has been lately directed in a lay journal to the onerous conditions under which nurses work, and especially those in hospitals. At a time when the "labor question" is receiving a great deal of attention, and on all sides the cry rises to reduce the number of working hours in every occupation, it is surprising that nurses have not previously found someone ready to champion their grievances. But little notice has apparently been given to the matter, even in medical circles. Yet this lack of interest cannot be excused by reason of the subject being unimportant. It appears that hospital nurses often work about fourteen hours a day. Rising about six, they are frequently on duty till about ten at night—only about two hours of this time being allowed for meals and open-air exercise. During a large proportion of this time they are either standing or walking about. As a consequence, flat-foot has been found to be unduly common in hospital nurses—an observation confirmed by inquiries from bootmakers in the immediate neighborhood of some of our large hospitals. During their long hours of duty, hospital nurses undergo considerable fatigue—both of body and mind—and, as a result, it is very common for them to deteriorate in physique. An unpleasant consideration in connection with hospital nursing is the fact that, in many hospitals the laborious services of the nurses are utilized to produce a pecuniary profit for the institution they serve. Thus, in some cases, probationers are admitted on payment of certain fees, and serve for perhaps a year without any wages. At some hospitals the probationers are very numerous, and only a small proportion of them can afterward obtain paid employment at the hospital at which they have been trained. Many of the large hospitals in London, also, now send out nurses to private patients at highly remunerative rates. The payments made by such patients, however, go to swell the hospital exchequer, the nurses simply receiving a small annual salary, together with their uniform and board and lodging in the hospital when not employed on private cases. A nursing institution in connection with a large hospital is, in fact, a valuable source of revenue to the hospital, as was lately admitted before the House of Lords Select Committee by a representative of one of the largest general hospitals. Similar arrangements are in vogue for paying the nurses at most of the private nursing institutions. In almost all of these the nurses are paid a very small annual salary, quite disproportionate to their earnings, and even where nurses are paid by the work they do, I have heard of from twenty-five to forty per cent. being deducted as a commission for the institution through which they obtain employment. It is, however, rather anomalous to find the methods adopted in private enterprises, avowedly established for the purpose of producing a livelihood to their owners, extended to public charities which are supported by voluntary contributions, and in aid of which it seems hardly fair to make nurses contribute their labor at ridiculously low rates.

During the past week the General Medical Council have been meeting—as is usual at this season of the year Perhaps the most important of their achievements on the present occasion is their adoption of the recommendation of their Education Committee, "that the course of professional study after registration should occupy at least five years, on condition that the fifth year should be devoted entirely to clinical work." The last is evidently a most important proviso, and it is not surprising to learn that, with this safeguard against the imposition of additional lectures on students, the propositions should have been unanimously accepted by the Council.

OUR PARIS LETTER.

THE CAUSE OF DIABETES—VISCERAL SURGERY—EXTIRPATION OF GALL-BLADDER—MASSAGE.

PARIS, May 23, 1890.

PROFESSOR LÉPINE, of Lyons, has enunciated a new idea, that diabetes is due to a deficiency of the diastasic ferment in the blood. He has demonstrated that the blood of a diabetic dog contains this ferment in much less quantity than the blood of a healthy dog. In a note that he has published on the subject, he announced that diastasis injected at a dose of one gramme under the skin of a dog diminished glycœmia, and, when injected at the same dose under the skin of a diabetic man, it considerably diminishes the glycosuria. This latter fact would appear to prove that the deficiency of the diastasic ferment is the real cause of diabetes. The following was the result obtained in his patient: Before injection, sugar, 35 grammes per litre; four hours after, 17 grammes per litre; six hours after (urine scanty), 4 grammes per litre; about twelve hours after, 14 grammes per litre. The author observes that, theoretically, the treatment of diabetes appears to be discovered. It remains to be determined

what the practical means are which would supply the deficiency of ferment, as the subcutaneous injection of ferment is an exceptional means, and which might perhaps cause accidents.

Medicine and surgery have certainly made great advances within the last few years, but surgery has made gigantic strides. Operations are now performed on the human body which no surgeon would have attempted only ten years ago. Thanks to anæsthetics and to antisepsis, operations are performed on the viscera with almost perfect impunity. At a recent meeting of the Academy of Medicine cases were related of a series of gastrotomy, laparotomy, hysterectomy, and nephrectomy that were performed by different surgeons. I have now to describe a rare operation recently performed by Dr. Bouilly, consisting of the extirpation by the Cæsarean section of an intra-uterine fibroma, which he related at the meeting of the Société de Chirurgie of April 30th last. The subject operated on was a woman, forty-two years of age, who never had a child, and who was affected since six years with metrorrhagia symptomatic of a fibroma. This tumor was developed not only into the abdominal cavity but into the vagina. The uterus was of the size of a gravid uterus of five months. In the vagina the existence of an enormous mass was discovered. The hysterometer disappeared entirely in the uterine cavity, and was withdrawn with facility. As regards an operation, it would have been impossible to remove the tumor piecemeal by the vagina, owing to its size and the loss of blood it would have caused. Abdominal hysterectomy would have been dangerous for the same reasons. Dr. Bouilly then decided upon extracting the fibroma by the Cæsarean operation, median laparotomy, displacement of the uterine mass, and fixing to the base of this mass a thick thread of india-rubber. The uterus was incised on its median line, being guided by the hysterometer. The fibromatous mass was free to a great extent, and it was detached very rapidly. The uterine tissue was very thin at its base of implantation, which presented a surface about the size of the palm of the hand. The upper portion of the tumor was removed by the uterine wound, for the lower portion the surgeon was obliged to divide a sort of isthmus which corresponded to the uterine neck. Immediately afterward the uterine tissue retracted and became about the size of a man's fist. The divers coats were then separately sutured, after having washed the uterine cavity with a solution of corrosive sublimate. Sixteen points of suture were applied, and the uterus was replaced in the abdominal cavity. Vaginal tampons were applied, and at the end of three weeks the cure was complete. This operation, concluded the author, may be performed only in certain cases, it represents the end of a work of enucleation commenced by nature. It had already been executed by certain surgeons, such as Martin, of Berlin, Doleris and Terrier, of Paris.

Dr. Terrier related a case of total extirpation of the gall-bladder which he had performed on a woman who presented, after some attacks of hepatic colic, a tumor situated on the inferior surface of the liver with induration. There was no jaundice. Cholecystitis was diagnosed and ablation of the vesicle was proceeded with. Laparotomy on the edge of the external rectus muscle, the adhesions which connected the bladder to the knuckles of intestine were separated, then an opening was practised which gave issue to a sero-sanguinolent liquid. In the bladder were a certain number of biliary stones, some of which were enclosed in the cystic duct. Attempts at extirpation were not pushed to any length for fear of rupturing the tissues, which were very friable. The extirpation of the vesicle gave rise to only slight hemorrhage. The edges of the abdominal wound were sutured to the tissues which surrounded the divided cystic duct in such a manner as to isolate the great peritoneal cavity from that of the cut extremity. A drainage-tube was placed in this small cavity and union was effected. The next day the patient was inundated with bile, which escaped through the drain. The supposition is that the pedicle, which was too much tightened, had ruptured. The fistula closed rapidly and the patient is considered to be cured.

Dr. Lucas-Championnière has just brought out a work which is a *résumé* of communications that he had made to the Société de Chirurgie on the applications of massage and mobilization in the treatment of fractures. The following is the therapeutic formula laid down by the author. The treatment the most efficacious of fractures is massage, it must be applied whenever it is possible to do so. The applications of massage may be divided into four classes: 1. Immediate and continued massage. This may be employed in fractures susceptible of slight secondary displacement, or where the displacement interferes but little with the functions of the bone, such as fractures of the radius or of the fibula, fractures occupying the neighborhood of joints, partial fractures of the elbow, fractures of the neck of the humerus, certain fractures of the condyles of the femur, and fractures above the ankles. 2. Massage before the limb is put into an apparatus, applicable to fractures of the wrist with great mobility, fractures above the ankles, fractures of the superior extremity of the humerus, and to the most mobile fractures. 3. The apparatus once placed is removed after two or three days, then methodical massage is practised, the apparatus is replaced, and is removed each day. 4. Immobility is necessary during some days, at the end of which time the union is sufficient to have the apparatus removed and massage practised The manœuvres of massage comprise three orders, viz., movements of exploration, movements of massage properly speaking, movements produced in the neighboring joints. The author concludes with a statement that he had obtained the following results: Rapid disappearance of the pain, the almost immediate re-establishment of the function of the limb, and the disappearance of the swelling, and the extreme rapidity of the formation of the callus. This is a novel method of treating fractures, but as Dr. Lucas-Championnière speaks of it in the most favorable terms, it is certainly worthy of a trial.

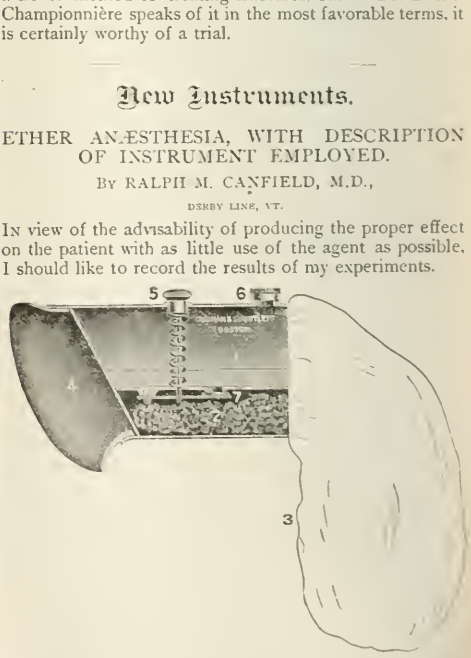
New Instruments.

ETHER ANÆSTHESIA, WITH DESCRIPTION OF INSTRUMENT EMPLOYED.

By RALPH M. CANFIELD, M.D.,

DERBY LINE, VT.

In view of the advisability of producing the proper effect on the patient with as little use of the agent as possible, I should like to record the results of my experiments.



Sometime since, being aware that the greater amount of ether used at operations was wasted, I was led to devise an instrument which should save this loss, and at the

same time, as it turns out, produce a more even anæsthesia, a very important point in delicate operations.

I will first describe my instrument and afterward give my experiments with it.

It consists of an ether-can holding one-half pound, with an inhaler attachment, as shown in the preceding cut.

1 shows the ether chamber, which is filled through the screw-button 6; 2 shows vapor-chamber with sponge intact; 3 is a cotton-bag wet with water to render it almost impervious to air and ether vapor, into and out of which respiration takes place; 4 is a rubber hood fitting over mouth and nose.

The ether is dropped on the sponge from the valve 7, operated by means of the presser-button 5 at will. The ether can thus be used drop by drop if so desired, saving all not actually absorbed in the lungs.

According to actual experiments, only one-tenth of the ether taken in an inspiration of the ordinary length is consumed, the rest is expired again, and in most cases lost.

This result was obtained by attaching a collapsed bag to a graduated pipette filled with ether at 0° Cent. and carefully warming till the bag was filled with vapor. An ordinary inspiration of the vapor was then taken and expired again into the bag at the usual velocity. The bag was then cooled to 0° again, and the condensed ether allowed to enter the pipette, when nine-tenths of that vaporized was found to be present.

The question naturally arises, as respiration is continued into and out of a closed chamber, whether the exhaled carbonic acid gas would collect in quantities to be injurious or not. Whatever theory may claim, the fact is, in practice it does not, and I think the explanation is, first, that the wet bag and sponge partially absorb the amount given off, and second, that the leakage around the face and through unclosed pores in the bag allows its escape.

Apart from the saving of expense in ether, which, as will be readily seen, is no small item, the fact that it is no longer necessary to literally saturate anæsthetist, operator, and all other parties near the operation, will, I think, be thoroughly appreciated.

The point of the advisability of producing anæsthesia as *quickly* as possible seems fairly defined, and as the oxygen in the ether ($C_4H_{10}O$) renders it without air life-supporting, the almost total exclusion of the latter is advisable. After the first choking sensation passes away, no further air is needed until complete anæsthesia is produced. I have many times produced complete anæsthesia in adults with two drachms, and hardly ever use more than four drachms. Continual anæsthesia can be procured in the average patient with about two ounces per hour.

Nearly all the struggling can be done away with by placing the inhaler on the face before allowing any ether to escape on the sponge, and giving a few breaths of pure air to allay fear. Then a few drops will quiet the first spasms, after which matters may be pushed as fast as possible.

An important feature is that by tightening the presser-button (5) the exit of ether is perfectly controlled by a velvet cork packing, and the whole awaits in readiness our need at a moment's warning.

The bag (3) folds and packs into the vapor chamber (2), so that our ether-can, with inhaler attachment only, occupies the space of about a Squibb's half-pound ether-can.

Almost all inhalers have been found to become cold, unless artificial heat is applied, and therefore useless when used for a long operation; but so little ether is used by this instrument that the latent heat required is very small, and the lungs of the patient furnish ample.

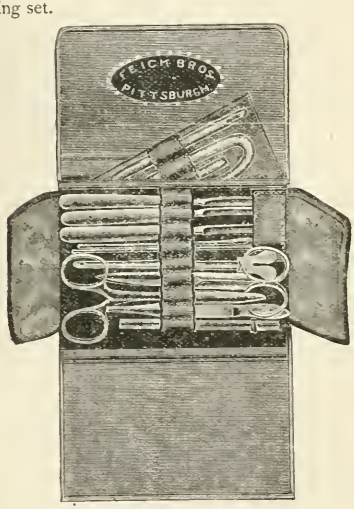
Since beginning the use of this instrument I have been troubled much less with the after vomiting and other usual sequelæ than formerly, and patients seem to rally much quicker. I have attributed these advantages to the small amount of ether used.

The instrument is manufactured by Messrs. Codman & Shurtleff, 13 and 15 Tremont Street, Boston, Mass., from whom it may be obtained.

A NEW ASEPTIC POCKET SURGICAL CASE

By I. P. KLINGENSMITH, M.D., F.S.S. LONDON,
BLAIRSVILLE, PA.,
SURGEON PENNSYLVANIA RAILROAD; MEMBER AMERICAN MEDICAL ASSOCIATION; MEMBER BRITISH MEDICAL ASSOCIATION; ETC.

NOTWITHSTANDING the fact that during the past year several valuable articles on the subject of pocket operating cases have appeared in your columns, we would nevertheless present for the consideration of your readers one which, in our surgical experience of fifteen years in railroad injuries and private practice, to our mind embodies all that asepsis, necessity, and utility demand. No man who practises surgery would for a moment think of relying upon a pocket-case when called to a case of injury of any magnitude, but would have recourse to his general operating set.



The following instruments are contained in this case: One narrow-bladed scalpel; one straight probe-pointed bistoury; one curved sharp-pointed bistoury; one pair dissecting forceps; one pair scissors (French lock); one hæmostatic forceps (Collini lock); two silver probes, one of them with eye; one director and tongue-tie; one silver porte-caustique; one soft rubber catheter, medium size; needles, silk, and catgut.

The case is made of morocco and lined throughout with leather, having no silk velvet upon which dirt or particles of dust can adhere; and is 5½ inches long, 3½ inches wide, and one-half inch thick; therefore is very compact and readily adapts itself to the coat pocket without bulging. In the leather-lined pocket, needles, silk, and catgut, folded in Lister's oil-silk protective or rubber tissue, are conveniently carried, together with a leather card having loops for the soft rubber catheter. The knives are made of one piece of steel, and all instruments are highly polished and nickel plated, having no roughened surfaces whatever. With perfectly aseptic instruments and bichloride of mercury tablets—which we take for granted are carried by everyone who makes any pretension to modern surgery—we are enabled to dispense with any form of metallic case, and we abandon the rather impracticable idea of attempting to carry silk and catgut in antiseptic solutions in a pocket-case. One great objection to pocket-case instruments, generally, is their small size and frailty, but the instruments contained in this case are of good size and admirably adapted to all practical purposes.

Dr. Francis Delafield, of New York, delivered the address in medicine at the Yale Commencement on Tuesday, June 24th.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 15 to June 21, 1890.

HORTON, SAMUEL M., Major and Surgeon. By direction of the Secretary of War, will visit the encampment of the Maine Volunteer Militia, at Augusta, Me., during the period of its encampment, June 30 to July 4, 1890, inclusive, for the purpose of instructing the medical department thereof in its duties in camp, and on completion of this duty will return to his proper station. S. O. 143, par. 5, A. G. O., Washington, D. C., June 19, 1890.

BYRNE, CHARLES B., Captain and Assistant Surgeon. By direction of the Secretary of War, is granted leave of absence for two months, to take effect July 1, 1890. Par. 13, S. O. 141, Headquarters of the Army, A. G. O., June 17, 1890.

GRAY, WILLIAM W., Captain and Assistant Surgeon. By direction of the Secretary of War, is granted leave of absence for four months, to take effect upon the final abandonment of Fort Maginnis, Mont. Par. 14, S. O. 141, Headquarters of the Army, A. G. O., June 17, 1890.

SWIFT, EUGENE F., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Spokane, Wash., and to report in person to the commanding officer, Fort McDowell, Ariz., for duty at that station, relieving Captain Marlborough C. Wyeth, Assistant Surgeon. Also, to report by letter upon arrival at his new station, to the department commander. Par. 10, S. O. 140, A. G. O., June 16, 1890.

WYETH, MARLBOROUGH C., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved from duty at Fort McDowell, Ariz., to proceed to Fort McIntosh, Tex., and report in person to the commanding officer thereof for duty at that station. Also, to report by letter, upon arrival at his new station, to the department commander. Par. 10, S. O. 140, A. G. O., June 16, 1890.

OWEN, WILLIAM O., JR., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for six months, to take effect when, in the opinion of his department commander, his services can be spared. Par. 12, S. O. 139, A. G. O., June 14, 1890.

APPEL, AARON H., Captain and Assistant Surgeon, Fort D. A. Russell, Wyo. Granted leave of absence for one month, to take effect on or about June 15, 1890, with permission to apply through Headquarters Division of the Missouri for an extension of one month. Par. 4, S. O. 42, Headquarters Department of the Platte, Omaha, Neb., June 10, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 21, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	6	3
Scarlet fever	41	11
Cerebro-spinal meningitis	0	1
Measles	341	10
Diphtheria	107	29
Small-pox	0	0
Varicella	18	0
Pertussis	1	8

A Doctor's Mistake Leads to a Wedding.—A strange case is reported from Iowa. A young woman living near Davenport, the daughter of a well-to-do farmer, was quite a belle and much sought after by the swains in the neighborhood. But there was one young man who was evidently the favorite, and though there was no actual engagement between them, it was generally understood that there would be one before long. Finally, however, the girl's mother noticed an increase in her size which led her to suspect that all was not as it should be. She charged the girl with having sustained improper relations with her admirer, but the imputation was indignantly denied. It was renewed again and again, till, though the girl continued to protest her innocence, her parents were forced by overwhelming evidence to believe that she had been deceived, and that she was attempting to deceive them. By way of setting the matter at rest the advice of the family physician was had. He confirmed the worst fears of the parents, and the latter then insisted upon the marriage of the couple, although the man denied any wrong-doing as emphatically as did the girl herself. As the months rolled by after the wedding and no change occurred in the daughter's condition, the parents began to think that possibly they had been a little hasty in their desire to preserve their child's reputation. Another examination was made, and it was learned that the poor woman had been unjustly accused by her parents, the trouble being due to the presence of a tumor and not to that of a child. An operation was performed, and now the interested parties do not know whether to accept the marriage as a fact or to have it annulled. Doctors' mistakes are sometimes more serious in their results than this was.

The Dangers of Dirty Streets.—In the last report of the New Jersey State Board of Health, Dr. Hunt devotes considerable space to the subject of the relation of clean streets to the health of cities. The care of the streets, he says, leads not only to the greater comfort of the citizens, but also concerns their health. He urges the necessity of good pavements and thorough drainage, and adds the following sensible advice concerning street cleaning: "Much of the surface cleansing of streets should be done at night, and even the sidewalks should not be swept in the face of those passing. Besides the discomfort, it is not appreciated what damage to health occurs from city dust. It is made up of dirty mud, of droppings of various kinds and of various forms of decayable matter. This in a finely triturated state mingles with the air and has to go into the lungs and stomachs of the people. A very dusty city is always more unhealthy. Water sprinkling in hot days, or when there is much dust, is much the choice of two evils; but if this has to be carried to the excess of causing undue moisture, it, too, becomes an evil. We desire to emphasize the injuriousness of city dust and to claim its abatement as a nuisance which interferes with the health not less than the comfort of the people."

Anonymous Communications. — We have received lately several communications from correspondents who neglected to send at the same time their names. It seems strange that it should be necessary at this late day to repeat the warning that no communication will receive attention unless it is accompanied by the writer's name and address. The name, of course, will not be published if the writer so request, but it must accompany the communication in all cases if the latter is to receive any notice.

A New Kind of Circumcision.—During the discussion of an address by Dr. Joseph Hoffman before the Alumni Association of the Medical Department of the Niagara University, at Buffalo, recently, it was suggested by Dr. Wilder, of Ithaca, that, in view of the dangers to which human beings are exposed from inflammation of the vermiform appendix, it be extirpated by aseptic laparotomy soon after the birth of the child.

Late Child-bearing.—Dr. E. F. Parsons, of Thompsonville, Conn., reports the case of a lady who was married at the age of fifty years, and gave birth to a female child after she was fifty-one years old.

INDEX.

Dry operations, 214.
Duckworth, Sir Dyce, notice of book by, 20.
Duodenum, perforating ulcer of the, 453.
Duval, Benjamin, death of, 563.
Dyspepsia, epilepsy, apparently dependent upon, 249.

E

Eager, William Blake, death of, 104.
Earache, relief of, 608.
Eclampsia, method of administering chloral hydrate in, 149; puerperal, treatment of, 412.
Eczema in elderly people, treatment of, 157; treatment of, 353.
Edebohls, George M., an improved antiseptic lock for surgical instruments, 310.
Edes, Robert T., tumor of the brain (thalamus and internal capsule), 578.
Education, collegiate, and the medical profession, 685; preliminary, new schemes for, 446.
Einhorn, Max, rumination in man, 554.
Eisler, Morris, death of, 472.
Electric light wire, injury of the larynx from, 105; prostration, 147.
Electricity and the human body, 596; in extra-uterine pregnancy, 136; in respiratory failure, 14; in the treatment of uterine fibroids, 165; static, actual work represented by a spark of, 608; static, the place of, in medicine, 609; therapeutic action of, 21.
Electrocution apparatus, testing the, 47.
Electrolysis, for uterine fibromata, 365; in diseases of the skin, 684.
Electro-therapeutic quackery, 63.
Elephant man, death of the, 591.
Ellis, R., justice to hospital graduates, 447.
Ely, John S., mummification: one of the results of retention of a dead fœtus in utero, 90, 106.
Embryocardia, 498.
Emperor of Germany, ear disease of the, 450.
Emmenagogue, pennyroyal as an, 417.
Empyema, etiology of, in children, 714; treatment of, 657.
Encephalocele, anterior, successful removal of, 374.
Endocarditis, a study of, 632; acute exudative, 541; chronic, heart lesions and heart symptoms of, 68; differential diagnosis of, 506.
Endometrium, corporeal, malignant disease of the, 369
Enemata, concentrated, of Epsom salts, 218.
English, D. E., concerning antisepsis in subcutaneous injections, 184.
Enuresis, atropine in, 630.
Epilepsy, a study of, 252; dependent apparently upon dyspepsia, 249; new operation for, 255; operations for, 250; temporary complete amnesia associated with, 405.
Epiphora, diagnostic significance of, 50.
Episcope, the electric, 592, 621.
Epistaxis, a simple method of controlling, 444.
Epithelioma of the hand, rare form of, 603.
Epsom salts, concentrated enemata of, 218.
Erysipelas, mechanical treatment of, 621; operative treatment of, 160, 290; poison of, possibly in human milk, 512.
Erythromelalgia, 656.
Ether, death from, 71, 245, 359.
Ethyl bromide, death from, 447.
Evans, William C., death of, 533.
Evans, Z. H., surgical treatment of puerperal peritonitis, 407.
Exophthalmos, diagnostic significance of, 50.
Expert medical witnesses, resolutions of the Kings County Medical Society respecting, 103.
Extra-uterine pregnancy, 692; electricity in, 136.
Eye, foreign body in the, for six years, 310; paralysis of the superior oblique cured by tenotony of the superior rectus of the same eye, 654; hemorrhage within the, consecutive to cataract extraction or to iridectomy for the relief of glaucoma, 613; primary tubercular disease of the, 428; working model of the, 281.
Eye diseases, spectroscopic examination of the blood in, 157.
Eyelids, lower, morning œdema of, diagnostic significance of, 50.
Eyes of school-children in France, care of, 27.
Eye-strain, causes and symptoms of, and a method for its detection, 277; relation of, to nervous phenomena, 1.
Eye-symptoms as aids to diagnosis, 49.

F

Facial hemiatrophy, progressive, with some unusual symptoms, 292.
Fairfield Medical College, sketch of the, 484.
Families, large, a premium for, 278.
Faradization in ascites, 97.
Fees, large, 45, 564, 639; professional, 509; in New York, 128.
Feet, artificial, in a case of arrested development, 452; sweating of the, 67.
Fell, George E., forced respiration, 225.
Female physicians for the insane, 187, 543, 638.
Femur, angle of the neck of the, 160; fractures of the shaft of the, treatment of, 601.
Fenwick, E. Harry, notice of book by, 247.
Fenwick, Samuel, notice of book by, 420.
Ferris, Albert W., poisoning with acetanilid, 187; the degree of hospital graduate, 696.
Fever and its treatment, 158; antipyretic, and alcohol in, 606; cause of, 26, 270; malarial, blood changes in, 664; relation of the glycogenic function of the liver to, 38.
Fevers, continued, of the South, 624.
Fibroid tumor of the broad ligament, 254; of the uterus, 705; of the uterus, electrical treatment of, 365; of the uterus, intra-abdominal enucleation of a, 213; sub-mucous and intra uterine, removal of, by enucleation and traction, 568.
Filaria sanguinis hominis, 624.
Finnell, Thomas C., obituary of, 420.
Fistula, operation on, in phthisical subjects, 364; uretero-uterine, 166.
Fithian, Enoch, ninety-eighth birthday of, 620.
Flannel, mercurial, 283.
Flat-foot, treatment of, by Thomas's method, 664.
Fleming, C. K., revision of our pharmacopœia and uniformity in dosage, 164.
Floods, sanitary results of, 128.
Fluhrer, William F., the advisability of wiring recent simple fractures of the patella, 645, 670.
Fluid extracts, standardize the, 619.
Fœtus, mummification of, in utero, 90, 106.
Foods, infant, 126.
Foot-ball casualties in England, 275.
Foot reflex from in-growing toe-nail, 190.
Forceps, naso pharyngeal, 483; obstetrical, 483; traction, a plea for the general adoption of, 690.
Foreign body in the eye for six years, 310; in the tissues of the neck for three months, 148.
Foster, M., notice of book by, 449.
Fowler, E. P., neurotic tumors of the breast, 179, 191.
Fracture of the condyle of the occipital bone, 443; of the maxillary bones, a new method of treatment, 611; of the patella, advisability of wiring, 645, 670; of the patella, treatment of, 313, 333; of the shaft of the femur, treatment of, 601; of the skull, trephining for, 443.
Frænum scissors, 109.
France, foreign doctors and dentists in, 276; medical students in, 200; native and foreign doctors in, 197.
Freudenthal, W., translumination of the larynx and of the antrum of Highmore, with demonstrations, 558.
Frey, H., death of, 219.
Friction-sound, perihepatic, 528.
Fridenberg, A. H., a simple method of controlling obstinate epistaxis, 444
Fullerton, Anna M., notice of book by, 332.

G

Gall-bladder, primary carcinoma of the, 541; rupture of the, 283; rupture of, in infants, 353; total extirpation of the, 736.
Gall-stones, succinate of iron in, 412.
Gastric affections, differential diagnosis of, 312.
Gastric juice, antiseptic function of the, 149.
Gastric ulcer, anomalous case of, 637.
Gastritis of phthisis, 199.
Gastro-enterostomy, for cancer, 448–472; for pyloric stenosis, 221.
Gastrorrhœa, periodic, 241.
Genito-urinary tract, primary tuberculosis of the, 106.
Germ diseases, phenic compounds in, 507.
German Congress for Internal Medicine, 532, 659.
German emperor, ear trouble of the, 70.
German Surgical Congress, 533.
Germany, dentists in, 148; medical practitioners in, 246; women doctors in, 155.
Germicidal action of blood-serum, and other body fluids, 85.
Gestation, ectopic, 692; electricity in, 136.
Gibney, V. P., report of two cases of death in young children during the administration of chloroform, 289.
Gillam, D. Tod, intra-abdominal enucleation of a uterine fibroid, 213.
Glaucoma, iridectomy for the relief of, intra-ocular hemorrhage consecutive to, 613; pathogeny of, 255.
Gluck, Isidor, the prevention of the toxic effect of cocaine, 707.
Glycogenic function of the liver, and its relation to animal heat, fever, and diabetes mellitus, 38.
Goethe, possible death of, from the influenza, 190.
Goldsborough, Charles B., death of, 100.
Gonococci, action of remedies on, 240.

Gonorrhœa, periurethritis dissecans as a complication of, 311; salol for, 239; sea-water injections for, 52; treatment of, 708.
Goodheart, James Frederick, notice of book by, 247.
Gosweiler, A. Van Hoff, electric prostration, 147.
Gottingen, new surgical clinic in, 47.
Grady Hospital at Atlanta, Ga., 128.
Grant, Frederick James, notice of book by, 534.
Graves, William W., report of a case of typhoid fever with an unusual complication, 118.
Griffin, E Harrison, the treatment for the radical cure of polypi of the nose, 727.
Grippe, see influenza.
Grove, B. F., advertising through a charity, 366.
Guillotine, antiquity of the, 110.
Guinon, Georges, notice of book by, 248.
Guiteras, Ramon, an experience with the influenza, 11; some features of the prevailing epidemic of influenza, 93; the dermatoses of influenza, 210.
Gull, Sir William Withey, death of, 127, 224; anecdotes concerning, 220, 246; successor to, 276.
Gunshot wounds of the abdomen, 661; of the brain, 663.
Guy's Hospital, Medical College of, 503.

H

Hadra, B. A., a case of relapsing appendicitis—removal of appendix—recovery, 269.
Hæmatocele, pelvic, treatment of, 278.
Hæmoptysis, cold air in, 461; non-tubercular, 15, 46.
Hair, removal of superfluous, 456.
Hale, Albert B., buried silk sutures, 527.

Hardaway, W. G., notice of book by, 534.
Hare, H. A., notice of book by, 19.
Hartwig, Mareel, raising the standard of the medical profession, 311.
Haven, Samuel Rush, death of, 533.
Hay in street cars, 48.
Hayes, Plym S., notice of book by, 132.
Hays, J. M., improved spray producers, 340.
Hayti, phthisis in, 40.
Headaches, from ocular defects, 217, 278; salt for, 46.
Health officer, the money value of a, 84.
Hearing, phonograph for testing the, 300, 339; standard scale for testing the acuteness of, 491.
Heart, a year's study of the, 356; enormous dilatation of the, 389; hemorrhage in the right ventricle, 78; lesions and symptoms referring to the, in chronic endocarditis, 68; preparation of a museum specimen of the, 390; presystolic sound of the, 4, 23; rapid action of the, 666; tricuspid stenosis, 41.
Heart disease, a new, 381; absolute milk diet in, 271; and marriage, 539; and obesity, 195; in early life, 4, 23; of the aged, 354; resulting from emotional causes, 511; therapeutics of, 308, 347.
Heart-failure cells, 363.
Heat, animal, relation of the glycogenic function of the liver to, 38.
Heath, Christopher, notice of book by, 248.
Hebrew hospital, proposed, 47.
Heineman, H. N., the therapeutics of cardiac disease, 347.
Heitzmann, Louis, bacteriological examination as an aid to clinical diagnosis, 492.
Helplessness, total, legal definition of, 426.
Hemiatrophy, progressive facial, with some unusual symptoms, 292.
Hemiglossitis, right-sided, 731.
Hemispheric vesicle, true homology of the mesal portion of, in the psauropsida, 343.
Hemorrhage, cerebellar, 53.
Hemorrhoids, operation for, 567.
Henschel, Edward K., death of, 276.
Hepatic disease, puncture *versus* exploratory incision in, 250.
Hernia cerebri, 270.
Hernia, lumbar, 633; radical operation for, 254, 633; radical operation for, in infancy and childhood, 662; remarkable cure of, 224.
Hernial sac, malignant growth in, 123.
Herpes zoster, in children, 222; treatment of, 83; ophthalmic, diagnostic significance of, 50.
Hiccough, nicotine for, 254.
Highmore, antrum of, translumination of, 558.
Hip-joint disease, management of, from an anatomico-pathological basis, 394.
Hip joint exsection, the result of, 307.
Hip-splint, the Thomas, 158, 311.
Hitchcock, W. W., notice of book by, 332.
Hoarseness, a lozenge to relieve, 6.
Holland, J. W., notice of book by, 20.
Home production, in favor of, 366.
Homœopath, definition of a, 244.
Hospital Book and Newspaper Society, 153.
Hospital graduate, degree of, 380, 447, 542, 696.
Hospital Graduates' Club, anniversary dinner of the, 590.
Hospital out-patient reform, 216.
Hospital Saturday and Sunday collection, 12, 190, 501.
Hospital service and politics, 69.
Hospitals, building of new, 99; pauper, of New York, 101.
Hot Springs of Arkansas, 383; and the treatment of syphilis, 463; the medical profession of, 190; United States Government hospitals at, 357.
Howe, Joseph W., obituary of, 711.
Hoyt, Ichabod Patterson, death of, 220.
Hudson, A. T., veratrum viride in tonsillitis, 527.
Hull, Henry V., obituary of, 504.
Humerus, fracture of the neck, diagnosis and treatment of, 159; osteochondroma of the, 162.
Humphrey, Laurence, notice of book by, 332.
Hutchinson, James H., obituary of, 48.
Hydatid cyst of the liver, 567.
Hyderabad chloroform commission, 152.
Hydrogen peroxide for the relief of bites from venomous insects, 148.
Hydrophobia, 626, 715; alleged cure for, 153, 379; autopsy in a case of, 389; deaths from, 46; prevalence of, 472; produced by the polecat, 664.
Hydrosalpinx, double, 695.
Hygiene with a vengeance, 15.
Hymen, excision of a tenacious, 278.
Hypnal, 475.
Hypnotics, dangerous, 190, 199.
Hypnotism, 530; employment of, for physiological investigation, 511; law concerning, in Sweden, 388; operation under, 11; personal observation upon the history and claims of, 691.
Hypochondriasis, 167.
Hypodermic injections, antisepsis in, 184.
Hysterectomy, supra-vaginal, 662.
Hysteria, following typhoid fever, 724; study of the sensory disturbances in, 597.
Hysterical paralysis, nature and treatment of, 567.
Hysterorrhaphy, a new method of, 136.

I

Illinois, regulation of medical practice in, 707.
Illinois State Medical Association, 592.
Incontinence of urine in children, 566.
Indecent advertisements, 186.
Indiana State Medical Society, 717.
Indigestion in functional nervous diseases, 161.
Inebriety, coffee, 683.
Infancy, radical operation for hernia in, 662.
Infant feeding, milk-sugar in, 630.
Infant foods, 126.
Infantile diseases, cranial compression as a factor in, 731.
Infantile mortality in Europe, 271; convulsions caused by the milk of a worried mother, 581.
Infants, rupture of the gall-bladder in, 353; stomach capacity of, 712; weight of, and the amount of food, 326.
Infection, carriage of, by medical men, 104; local and general manifestations of, 412.
Infectious diseases, disinfection during and after, 233; liability of physicians to, 510.
